There are mental diseases, however, in which aggravated damage to the heart and circulation follows from the nature of the psychosis itself, as when an elderly patient suffering from cardiac and arterial disease becomes so intensely agitated and restless because of his profound emotional state that his circulation and the integrity of his heart become disturbed. Under such circumstances, I have weighed the risk of treatment against the risk of the disease and have given the treatment on the basis that the risk was warranted. There are 4 such cases in my records, of which I cite 2. One patient, a man with severe cardiac disease, frequent attacks of angina pectoris and one previous attack of coronary thrombosis, who presented the picture of a very severe agitated depression, recovered promptly after eight electric-shock treatments and has remained well; electrocardiographic studies made before and after treatment showed no change in the condition of his heart due to the electric shock. The other patient, a woman with myocarditis that warranted the use of digitalis in maintenance dosage, received seven shocks without any apparent damage to the heart or circulation, although her mental condition was only temporarily relieved. It can safely be stated that an ordinary degree of cardiac and vascular change need not be a contraindication if the psychosis warrants treatment.

Treatment was also given to a woman with a severe case of diabetes requiring 60 units of insulin a day. She received nine shock treatments over a considerable time, with no evidence of

change in the diabetic state and with marked improvement in the mental state. There was a slight temporary change in the color of the urine after each treatment.

One patient with pernicious anemia, with a red-cell count of slightly over 2,000,000 and a hemoglobin somewhat under 50 per cent and with other evidence of vitamin deficiency, was treated (four shocks) with good results and without any effect on the pernicious anemia except perhaps in the direction of improvement, since her appetite returned and she ate a greater amount and a greater variety of food.

One case of Paget's disease in a man of over seventy was also treated (five shocks) by this method, without damage to the bony structure.

I believe that the technic used plays some part in the low rate of injury and that the physiology of electric-shock treatment is a significant factor in explaining the fact that moderate organic disease of the heart and other organs of the body is not a contraindication to the treatment. I have been very careful in the use of sandbags and a firm bed to support the back. Pillows have routinely been placed under the knees, so that it is impossible for the patient to get his feet down to the table and thus to put an extra strain on the back and other parts. Great care has been taken to prevent the shoulders from rotating outward and upward. A gag, made of felt and carefully inserted and watched during the procedure, has prevented any dislocations of the jaw; in fact, none have occurred for over a year.

The fact that with proper precautions few serious injuries take place is confirmed by most other reports. For example, the Boston State Hospital, which has given a large number of electric-shock treatments in the past year, has an exceptionally fine record so far as injuries are concerned. The method, therefore, may be declared safe. This, I repeat, does not mean that it is to be used indiscriminately, or without proper hospital conditions.

Unlike Metrazol, the electric-shock treatment causes a fall in the blood pressure. For a very short time, the patient is pulseless, but within a few seconds the pulse returns. There is less cyanosis than with Metrazol. There is no sweating. There is very little evidence of vasomotor disturbance. The gastrointestinal tract does not seem disturbed. There is rarely any nausea or vomiting, and there is no interference with the function of the bladder.

It has been recorded that there is a possibility of spontaneous epileptic attacks following shock treatment. The literature on this point is very scanty, and the evidence of such a result is not at

all conclusive. In fact, Kalinowsky et al.^{3,4} believe that electric shock offers a method of treatment for epilepsy. I have seen only 1 case in which there were epileptic attacks of minor type following treatment. This occurred in a fifty nine year-old woman with arteriosclerosis. After the treatment had been concluded, she had on successive days two short attacks of unconsciousness closely resembling those seen in arteriosclerosis, with some convulsive twitchings of the face and arms. There was no evidence of subdural or subarachnoid hemorrhage. In my opinion, the danger of setting up epilepsy by electric shock can be discounted.

Indications for Treatment

In considering the type of case that responds to this treatment, one must remember that psychiat-

only approximations to roughly delineated clinical syndromes, and disappointment in the result or even the unexpected good result cannot at present be explained.

In general, one may say that the electric-shock treatment is of little value in the fully developed schizophrenic state, with splitting of personality, hallucinations, delusions of reference, and negativistic or catatonic reactions—more especially, when the condition has lasted for years. Cases that are diagnosed as early schizophrenia sometimes do remarkably well, but the question of differential diagnosis is essential in an interpretation of the results. Thus, in one of my cases that had lasted for two years and had been diagnosed as schizophrenia, very good results were obtained with four shocks, and the recovery has lasted for six months. However, a study of the family

ric diagnosis has not reached the stage where it is possible to discriminate with any exactness between the various types of so-called "functional psychoses," such as schizophrenia, manic depressive psychosis, involuntal melancholia and the unclassified depressions, and the various severe neuroses. There is an abundant literature concerning this difficulty. Thus, a case diagnosed as schizophrenia by one clinician may be diagnosed by another as a marked depressive retreat. A patient who presents a neurosis at one stage of his mental disease may later show schizophrenia or some form of the depressive psychoses. Moreover, depressive psychoses may be substantially different, even though with the present inadequate methods of diagnosis and study they show a similar general clinical picture. Therefore, all statements regarding the value of this treatment can be regarded as

history shows cases of manic-depressive psychosis, and the study of the past history of the patient herself is not at all conclusive of schizophrenia. It has been stated by some writers that schizophrenic patients need a large number of shocks for improvement or recovery. In 3 of this series of cases, more than fifty shocks were given, with no fundamental improvement in these well-marked schizophrenic states, the average number of shocks given in the other diagnostic groups being about seven, or even less. Conduct improvement often takes place, and temporary improvement is remarkably frequent. Unfortunately, in the vast majority of cases of clearly differentiated schizophrenia, the patient slips back into his previous state.

Electric shock is also of little advantage in the paranoid psychoses. Some cases with paranoid

coloring, that is, patients whose underlying state is fundamentally depressive, do very well. The patient believes himself to be persecuted, but when this delusion is analyzed, it is found that he is being persecuted because of his derelictions or for his good rather than because of the gratuitous hostility and malevolence of others.

In the obsessive-compulsive neuroses I have obtained no permanent benefit by the use of this method. The literature, on the whole, bears out this statement.

The involutional melancholias, with clearly marked depression, great agitation, anxiety, feelings of unreality or nihilistic delusions, on the whole do well with this form of treatment. This is the unanimous conclusion in the literature, and is borne out by my own experience (Table 1). One sometimes sees improvement in these cases after one, two or three treatments. The sequence of events seems to be that sleep is first restored, and that, as the memory becomes somewhat impaired, the delusions disappear and a genial and jovial mood replaces the melancholia. In a large number of cases, this improvement persists. There are relapses, however, and the treatment can by no means be called a cure. Nevertheless the improvement is so prompt and lasts in so many cases for so long that this can be called the best approach to the symptom complex at present.

Experience with senile melancholia in cases occurring after the age of seventy is insufficient for any conclusions. In 2 patients whom I have treated, there was marked temporary improvement, but no subsequent permanent gain.

The result of treatment of the depressive phase of the manic-depressive psychosis is similar to that of the individual melancholias. There is immediate improvement with treatment, usually after the third or fourth shock. The attack is frequently remarkably shortened in duration and intensity, and even where there is some slipping back, it does not generally reach the former level of despair and death seeking. It must be stated at this point, however, that when the attacks are frequent,—that is, when the cycle repeats itself every few months or even more frequently,—electric shock does not seem to me to be warranted. Part of the result of the treatment of the depressive states is the appearance of a mild euphoria. A manic state often supervenes, usually of less intensity than the depression, and often without any definite handicap to the patient. When the manic attack may appear at any time, however, it seems inadvisable to administer the electric shock. This statement is made because the manic attack itself does not seem in any fundamental way to be improved by shock therapy. Conduct improve-

ment takes place, and a very wild patient is more easily managed. Within a week or two after the treatment has been terminated, the patient becomes as manic as ever. I have therefore discontinued the electric-shock treatment in the manic states, except when its use lessens the strain of the arduous care of the patient.

Very good results are obtained in cases of chronic depression, such as I⁷ have elsewhere described as the "anhedonic state," and one cannot explain these cases on the basis of coincidence. In several such cases in my records, patients have remained anhedonic for several years and without improvement, despite the type of treatment used. Following a few shock treatments, the mood alters *pari passu* with the number of shocks given and the appearance of some impairment of memory. In some cases, a moderate exhilaration appears and persists for a long time, but is not troublesome.

Electric shock has not given marked relief in the neuroses, especially the anxiety neuroses that are marked by paresthesias occurring under excitement, with a sense of marked visceral disturbance, either of heart, head or other parts, and with marked fear localized as phobias or as diffuse agitation and anxiety. In these cases, the patient, usually being noncommittable, refuses to continue the treatment after a few shocks are given.

At this point, it is safe to say that the statement made in the literature that there is no fear of the treatment is not correct; there is less than with Metrazol shock, and often enough the individual treatment is not at all remembered. In the relatively sane patients, the whole matter of repairing to a hospital, of becoming unconscious and of a period of agitation and loss of memory afterward becomes linked up with the idea of treatment, and a definite association fear of the treatment develops. In the markedly psychotic cases, no such fear seems to be experienced.

I have not been able to treat in any consecutive manner such conditions as neurasthenia and hysteria. In a few chronic cases, I have attempted to carry out the treatment, but the patients have themselves put an end to this by refusing to undergo more than one, two or three shocks.

Summarizing the indications, one may say that when a disturbance in affect or mood is the main psychopathologic feature, electric-shock treatment has a very reasonable prospect of bringing about marked improvement, recovery or, at the worst, remission. This includes the depressive states, the anhedonic states and the cases of involutional melancholia. This is not true, however, of the affective disturbance called the manic phase of manic-depressive psychosis. In functional or nonestab-

lished pathologic mental diseases, such as schizophrenia, the paranoid psychoses, the obsessive compulsive states and the anxiety neuroses, the results have not been particularly gratifying. Temporary improvement is common, permanent or durable improvement is not frequent. When the differential diagnosis is in doubt,—that is, when it is difficult to differentiate a mental disturbance of the schizophrenic type and one belonging on the whole to the mood and affect disorders,—it is justifiable to use this method, since on the whole no harm is done and the prognosis is so poor as to warrant anything that offers hope.

In Table 1, the diagnoses include a great variety of depressions that some other workers might perhaps classify with the manic depressive states. The difference is that certain classic phases of the manic depressive state did not occur in this group of patients. Most of them were not retarded, a good many had no delusions of any kind, and some were definitely not psychotic in the technical sense. The main feature in common was in at least disturbance of a depressive nature.

It is necessary to define the term 'anhedonia unreality syndrome'. By this is meant a state in which there is complete lack of desire and satisfaction for the visceral enjoyments, such as eating, sleeping and sexual relations, as well as a failure in energy and the capacity to work, linked with a feeling of unreality sometimes related to the outer world and sometimes including the patient himself. It is possible that this group of cases is also allied to the manic-depressive state. The patients are not insane in the usual sense and have good insight.

By the term 'slight improvement' is meant conduct alteration and a lesser expression of the psychosis. 'Temporary improvement' goes farther: the patient seems quite well for a short time—two or three weeks to two or three months. Moderate improvement means that the patient shows conduct improvement and a general lessening of psychotic and mental symptoms directly following the treatment and maintained indefinitely. By 'much improvement' is meant an extension of this classification further, difficult to make quantitatively but representing a clinical impression. 'Recovery' means that the particular attack disappears and, so far as can be seen, there are no mental signs whatever.

SUMMARY

The injuries resulting from electric shock therapy, and the risks encountered, are discussed. The indications and contraindications in various neuroses and psychoses are considered. Experience with this form of therapy in 123 cases of mental disorders is presented.

CLINICAL NOTES

ACUTE DISSEMINATED LUPUS ERYTHEMATOSUS ASSOCIATED WITH FINGER LESIONS RESEMBLING LUPUS PERNIO*

REPORT OF A CASE

JOHN G. DOWNING, M.D.,†
AND SALVATORE J. MESSINA, M.D.

BOSTON

THE following case is of interest because the initial lesions were seen on the tips of the fingers, when a diagnosis of lupus pernio was made. However, the typical butterfly lesion of the face soon appeared, and the patient complained of abdominal pain, nausea and vomiting, and muscular and joint pains; these symptoms clinched the diagnosis of lupus erythematosus disseminatus.

CASE REPORT

G. C., a 15-year-old girl, was first seen at the Medical Clinic of the Out-Patient Department, Boston City Hospital, in December, 1938, complaining of loss of energy, general malaise and stiffness and soreness of the fingers of both hands for the previous few weeks. The patient was referred to the Skin Clinic in January, 1939. Physical examination revealed erythematous infiltrations on the flexor and lateral aspects of the fingers. These areas were rather tender. The hands were cold and clammy. A diagnosis of lupus pernio was made.

During the next week, ulcerative changes were observed on the skin of the fingers. The volar surface showed several round to oval lesions 2 or 3 mm. in diameter, with smooth raised red edges and central scaling depressions. Physical examination was negative except for the fingers. Two weeks later, a faint butterfly lesion on the face was evident. X-ray examination of the hands, feet and lungs was negative. Tuberculin tests in dilutions of 1:10,000 and 1:1000 were negative. The blood Hinton reaction was positive. Biopsy showed hyperkeratosis and no atrophy of the epidermis, acanthosis, and elongation and matting of the rete pegs. The corium showed lymphocytic and perivascular infiltrations; there was no evidence of true tubercles. At this time, weekly injections of 1 cc. of bismuth were begun. After eight such treatments, there was a marked improvement, the central depressions of the lesions of the fingers becoming less evident and the erythematous color fading to normal skin color. A blood Hinton reaction was doubtful, but both Kahn and Wassermann reactions were negative.

The patient was admitted to the hospital in June. Three days before admission, she had noted fever, without chills. In the mornings, there was mild nausea, and vomiting occurred soon after eating. There was mild, cramplike abdominal pain.

Physical examination revealed an erythematous patch,

*From the Department of Dermatology and Syphilology of the Boston City Hospital and of Tufts College Medical School.

†Visiting physician for diseases of the skin, Boston City Hospital.

3 cm. in diameter, above the bridge of the nose, herpetic lesions about the nose and mouth, and hemorrhagic oval lesions, 5 mm. in diameter, on the hard palate. The lungs were clear, and examination of the heart revealed no murmurs. The abdomen showed generalized and rebound tenderness. The liver and spleen were palpable at the costal margins. The volar surface of the fingers showed reddish-purple, oval, depressed atrophic patches, 5 to 10 mm. in diameter. The hospital stay was characterized by an elevated temperature (103°F.), which gradually fell to normal in 2 weeks. The daily urines showed albumin except for two specimens. The white-cell count, which was 2300 on admission, gradually rose to normal by the 7th hospital day. The patient became asymptomatic at the end of the 2nd week, and was discharged on the 23rd day with a diagnosis of lupus erythematosus disseminatus.

The patient returned to the Skin Clinic and was again given 1 cc. of bismuth weekly. In November, 1939, she was seen at the Vascular Clinic, and a diagnosis of Raynaud's disease was made. In May, 1940, she was exposed to the sun and developed the typical butterfly patch of lupus erythematosus on the face. Two weeks later, she began to have soreness of the throat and morning bleeding from the mouth, gums and throat, accompanied by a weak and feverish feeling. Hospitalization was advised.

The patient was readmitted to the hospital in June. The face showed a red, slightly raised eruption confluent except at the periphery, where there were isolated papules, not indurated, blanching on pressure, with prominent follicles on the involved area, and a roughly butterfly distribution involving the nose and cheeks and extending up to the ears and the sides of the face and over both eyebrows. There were slightly indurated papules becoming confluent over the upper lip, involving both the skin and the mucous membrane. Multiple small circinate red lesions 1 to 3 mm. in diameter were seen over the gums, hard palate and gum margins. The thorax and abdomen showed lesions like those on the fingers. The tongue was coated and fissured. The teeth were carious. The tonsils were moderately enlarged but showed no redness; the hair showed evidence of alopecia. The pupils were slightly irregular but reacted to light and distance, and in the right fundus, a fading flame-shaped hemorrhage was observed; pea-sized axillary and inguinal nodes and bean-sized tonsillar nodes were palpated; the trachea was in the midline. The lungs were clear to percussion and auscultation. The heart was enlarged, rapid, regular and overactive, and the pulmonic second sound was greater than the aortic; there were blowing systolic murmurs at the apex and in the pulmonic area. The abdomen was flat, with no spasm or tenderness. The liver was felt 3 cm. below the costal margin; the edges were sharp and soft. The spleen was 1 cm. below the costal margin in the left lateral position. The reflexes were physiologic. The blood pressure was 104/64.

Daily examinations of the urine showed a specific gravity of 1.010 to 1.020, an acid reaction, and slight traces to traces of albumin in all but three specimens. The sediment contained a few to many white blood cells, usually in clumps, very rare red blood cells on only one occasion and coarse granular casts just before death.

The hemoglobin, which was 75 per cent on admission, fell to 45 per cent 3 days before death. The red-cell count was 3,800,000 on admission and 2,700,000 before death. The white-cell count varied between 5200 and 5000; differential counts on admission showed 78 per cent polymorpho-

nuclears, 17 per cent lymphocytes, 1 per cent monocytes and 5 per cent young forms. The blood Hinton reaction was positive on three occasions and doubtful twice. The blood Wassermann and Kahn reactions were negative on two occasions. The nonprotein nitrogen was 41 mg per 100 cc. on admission, rising to 60 mg 4 days before death. The total protein, which was 6.6 gm per 100 cc on admission, was 6.5 gm 10 days later. The albumin globulin ratio was 3.9:2.6. The blood sodium was 133 mg per 100 cc., 2 weeks later, it was 130 mg. The chlorides were 571 mg per 100 cc. The potassium was not recorded. The calcium was 8.5 and the phosphorus 5.1 mg per 100 cc. The phosphatase was 32 Bodinsky units. Four blood cultures revealed no growth, but one culture showed streptococcus, subsequent cultures were negative. The phenolsulfonephthalein was 44 per cent in 2 minutes. The Widal test was negative. The clotting time was 15 and the bleeding time 3 minutes. The mean corpuscular volume was 93 per cent. The prothrombin time was 31 and the coagulation time 13 minutes. The icteric index was 7, the urobilinogen 1.8 mg per 100 cc., and the sedimentation rate 17. Three stool examinations revealed negative guaiac reactions.

A chest plate revealed clear lung fields.

An electrocardiogram showed normal sinus rhythm, a PR interval of 0.16 second and a QS complex of 0.06 second, T_1 was upright, T_2 was flat, and T_3 and T_4 were inverted. The left ventricular predominance was interpreted as showing myocardial disease.

The patient was hospitalized for 26 days, during which she steadily failed. The temperature varied from 100 to 102°F daily. There was mild generalized abdominal pain, with nausea and intractable vomiting. The lesion on the face faded somewhat, but the mucous membrane lesion progressed and became confluent. Frequent nosebleeds and hemorrhages from the gums were present. At the end of the 3rd week, the patient was having severe gastro-intestinal symptoms, vomiting and abdominal pain, hyperpyrexia (104°F) and increasing asthenia, she had lost 10 pounds since admission. The blood pressure rose somewhat with administration of 10 mg desoxycorticosterone daily. On the 26th hospital day, the patient went into peripheral vascular collapse, and death followed in a few minutes. No autopsy was performed.

This case of acute disseminated lupus erythematosus is reported because of the unusual sequence of symptoms and physical signs shown by the patient, and because the opportunity to follow a patient from what is deemed clinically a benign symptom complex to a later fatal disease is rare. The uncommon but confusing laboratory findings, in view of state laws demanding serologic examinations before marriage, should be of interest to all physicians. This case shows that the dermatologic eruption was only a physical sign of a serious systemic disease that was further complicated by abdominal symptoms suggesting the need of surgical interference.

THE USE OF IODINE TO DELINEATE A SAFETY ZONE IN THE RECTUM*

DAVID C. DITMORE, MD†

BOSTON

WHEN or by whom iodine was first used as a vital tissue stain, I do not know. However, the fact that certain cells take up the dye more readily than others was first brought to the attention of the medical profession by Schiller‡ in his work on the early diagnosis of cancer of the cervix. I have found that the affinity of the tissues just above the pectinate line of the rectum for the simple tincture or the compound solution of iodine varies so decidedly that the use of either is of great assistance when one is working in this area. In fact, there is definitely outlined the distal border of a portion of the rectal wall that, since it has little tendency to bleed and does not respond to painful stimuli, may be termed the "safety zone." The existence of this zone is so manifest and the test to locate it so simple that I hesitate to claim anything new in it, but general knowledge concerning the phenomenon is lacking, I am quite sure, and for that reason I shall describe the technique of its demonstration.

After a swab of cotton on an applicator is dipped into the iodine, it is withdrawn and held momentarily against the mouth of the container so that any excess fluid may escape. The area to be investigated, already isolated in the anoscope, is then prodded gently with the iodine soaked swab. If no change in color appears, the anoscope is slowly withdrawn with the free hand, while prodding with the iodine swab is continued. At some point above the pectinate line, the tissue will be seen to become deep black.

The stained area follows no uniform pattern. In some cases, there may be a continuous or broken band no more than 2 or 3 mm in width tracing the upper border of the pectinate line. On the other hand, the stained area may be from 15 to 20 mm in width, with the upper border very irregular. Regardless of the extent of the heavily stained tissue, the operator may, by confining himself to the zone immediately proximal to it, proceed with minor surgery without fear of complications such as excessive bleeding, pain and external edema. He must, of course, observe ordinary surgical technique.

*From the Department of Proctology, Boston University School of Medicine and the Massachusetts Memorial Hospital.
†Instructor in proctology, Boston University School of Medicine, proctologist at Massachusetts Memorial Hospital.

‡Schiller, W. Zur klinischen Frühdiagnose des Portalkarzinoms. *Zentralblatt f. Gynäk.* 52:1886-1892, 1928.

I am not qualified to discuss the mechanism of this staining reaction. Much has been written about it. Everyone seems to agree that columnar cells do not take the stain, whereas cuboidal or squamous cells with a high content of glycogen stain readily. I have never seen it mentioned that highly vascular tissue stains more readily than avascular tissue, but this seems to be true, at least in the lower rectum.

The practical values of this test are many. For example, in the safety zone, biopsy, insertion of a hypodermic needle and removal of small benign tumors are simple procedures. Proximal or distal

to that area, the same operation may cause much unhappiness both to the physician and patient.

CONCLUSIONS

Variations in the affinity for iodine of normal tissue cells of the anorectum are as striking as those described by Schiller in his work on carcinoma of the cervix.

Taking advantage of this property, one can roughly locate the pectinate line and establish a safety zone in which minor surgical procedures may be carried out.

MEDICAL PROGRESS

RADIATION THERAPY

RICHARD DRESSER, M.D.*

BOSTON

THE recent advances that have been made by physicists and engineers in the construction of x-ray generators have placed at the disposal of the radiotherapist a wide variety of wave lengths in intensities greater than were dreamed of a decade ago. It is natural that some confusion regarding the relative merits of these wave lengths should exist, not only in the minds of practitioners but also among radiologists themselves. Although the clinical results of radiation treatment can be evaluated only after years of painstaking observation, the intelligent application of roentgen rays or radium rays should be based on a knowledge of their physical properties as well as their biologic effects. The physics of radiology has been set forth simply and concisely in a recent treatise by Robertson.¹ A review of this work should help the practitioner to understand some of the problems that confront the specialist in radiation therapy.

Radium is an element that is continually disintegrating. In the process of decay, three types of energy are given off—alpha, beta and gamma rays. If the rays from a radium source are submitted to the action of a strong magnet, the alpha rays are deflected in one direction and the beta rays in the opposite direction; the gamma rays are unaffected by the magnetic field. The alpha rays are actual particles of matter bearing a

positive electric charge. The beta rays, which are likewise particles of matter, carry a negative charge. The gamma rays have no mass, but are electromagnetic vibrations. The alpha rays may be disregarded in therapeutic work, since they have little penetrating power and are filtered out by the wall of the radium container. The beta rays have considerable penetrating power and are frequently used, particularly in the field of dermatology, for the treatment of superficial lesions. The gamma rays are the most important of the radium rays. They have essentially the same properties as x-rays but are much shorter and more penetrating than the x-rays in common use. Recently, it has been possible to produce x-rays that are as short or even shorter than the gamma rays of radium.

Radium element is most commonly used in the form of one of its salts, either the sulfate or chloride. Metal tubes are filled with the salt and sealed off at either end. Frequently, the tube has an eye at one end and a point at the other, forming what is known as a radium needle. A special type of applicator may be inserted into a tumor mass and withdrawn, after the required dose has been given, by means of a string threaded through the eye. It is often desirable in radium treatment to exclude the beta rays, leaving only penetrating gamma radiation. This is done by the use of a position of a metal screen or filter between the radium source and the tissue irradiated. It is now common practice to make the wall of the container of some metal of sufficient density and thickness to remove all beta radiation without adding screening. The commonest filters, listed in a

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress: Annual, Vol. III, 1942* (Springfield, Illinois: Charles C. Thomas Company, 1942. \$5.00).

*Radiologist, New England Medical Center, and Free Hospital for Women, Brookline; assistant radiologist, Massachusetts General Hospital.

of their effectiveness, are platinum, gold, lead, silver and brass. Radium dosage, when the element is used, is expressed in milligram hours: that is, the number of milligrams employed multiplied by the time of application in hours. Thus, 10 mg. applied for five hours would give a dose of 50 mg. hr. Likewise, 25 mg. applied for two hours would give the same dose.

Another form in which radium is used is known as radium emanation or radon. Radon is a gas that is given off from radium and, by means of a specially designed pumping and purifying system, can be collected in capillary tubes of glass or gold. The development of the so-called "radium emanation plant" was due in a large measure to the researches of the late William Duane, professor of biophysics at Harvard University. After the capillary tubes have been filled with radon, they are cut into small sections, which are automatically sealed in the process of cutting. These capillary sections are known as radon seeds or implants. They emit both beta and gamma radiation; however, if a gold capillary is used, a large percentage of the beta radiation is filtered out. The great difference between radium element and radon is that the former takes one thousand six hundred and ninety years to degenerate to half strength, whereas the latter becomes inactive for practical purposes in about thirty days. One makes the application of radon seeds by placing the implant in a suitable trocar. The trocar is pushed into the neoplasm to the desired depth, and a stylet then pushes out the seed. When the trocar is withdrawn, the seed remains in the tumor. Radon dosage is expressed in millicurie hours, 1 mc. hr. being equal in intensity to 1 mg. hr. Each millicurie of radon delivers, in its decay period of thirty days, 130 mc. hr. Thus, if a seed of 2-mc. strength is inserted, the total dose is figured as 260 mc. hr. Radon seeds may be employed to advantage in locations where it would be difficult to insert or to hold element needles in place,—for example, in a carcinoma of the tonsil.

Credit for the development of an x-ray tube whose output can be accurately controlled is due Coolidge, former director of the research laboratories of the General Electric Company. When a wire is heated to incandescence in a vacuum tube, small negative particles of electricity are liberated about the wire. This is known as ionization by heat, or the Edison effect. By application of a high-voltage current to the tube, these ions may be drawn away from the wire filament and made to move at high velocity toward the target or anode of the tube. The impact of the electrons against the anode, which is usually a block of tungsten, results in x-ray production. It has already been noted that the commonly employed

roentgen rays are identical with the gamma rays of radium except in wave length.

The physical properties of x-rays may be considered from the standpoint of intensity or quantity, and of quality. If the amount of current applied to the tube is varied, the amount of x-ray emitted varies in direct proportion. If, however, the voltage of the current is varied, the x-ray output varies approximately as the square. More simply, if the voltage on the tube is increased from 100,000 to 200,000, all other factors remaining constant, the x-ray production will be quadrupled. X-rays and light rays follow the same law in regard to distance: that is, the intensity varies inversely as the square of the distance. For example, if one assumes that it takes ten minutes to administer a certain x-ray dose at a distance of 25 cm. from the source of radiation to the skin of the patient, and if this distance is doubled,—that is, increased to 50 cm.,—not one half but one fourth the amount of radiation reaches the patient. It then takes not ten but forty minutes to give the same x-ray dose.

To explain variations in the quality of radiation, one may draw an analogy between a beam of x-rays and a beam of sunlight. When sunlight is passed through a glass prism, the well-known spectrum results, because of a breaking up of the beam into its constituent wave lengths. The violet band at one end of the spectrum represents the shortest visible wave lengths, whereas the red band at the opposite end represents the longest visible wave lengths. By passing an x-ray beam through a prism, let us say of rock salt, one can obtain an analogous spectrum. This, of course, is not visible, but the various bands can be recorded by photographic and other methods. It will be found that the beam is not homogeneous but is composed of a variety of wave lengths. By raising of the voltage on the x-ray tube, shorter wave lengths are added to the beam; there is more "violet" radiation if one uses the analogy of the light spectrum. If the potential is increased to between 2,000,000 and 3,000,000 volts, the short wave lengths of the beam are identical with the shortest gamma rays of radium. If one wishes to employ only the short wave lengths of an x-ray beam, the longer rays must in some manner be excluded. This is done by the use of filters, as in radium work. The common filters are lead, copper, a combination of tin and copper, and aluminum. Lead is used in filtering rays produced at 1,000,000 volts and upward. Copper, or tin and copper are used for rays of 200,000 to 500,000 volts, and aluminum for rays produced at 100,000 to 150,000 volts.

X-ray dosage is commonly expressed either in

terms of the visible effects on the skin or by a physical measurement of intensity known as the roentgen unit (r). If a certain amount of radiation is given to the skin, a mild redness appears in ten days to three weeks after exposure. The amount of radiation necessary to produce this effect is called the "erythema dose." A slightly smaller amount causes epilation of a hairy area, and is known as the "epilation dose." X-rays passing through the air cause an electrical upset in the atoms that is termed "ionization." The amount of ionization is directly proportional to the intensity of the x-ray beam. The roentgen unit is based on a physical measurement of the amount of ionization occurring in 1 cc. of air. It has become the internationally accepted standard of x-ray dosage.

The treatment of superficial lesions concerns chiefly x-rays of long wave length — that is, the relatively nonpenetrating variety. Many benign dermatologic conditions, together with cancerous or precancerous lesions of the skin, can be adequately handled by rays produced at not more than 100,000 volts. Any good radiographic machine equipped with the proper tube is entirely adequate to handle such cases. If, however, a lesion is situated at some distance below the surface, it is obviously impractical to attempt treatment with 100,000-volt x-rays whose energy is largely dissipated within the first 2 or 3 cm. of tissue. One must resort to shorter wave lengths, which necessitate high voltage for their generation. A second factor of equal significance in the treatment of deep-seated lesions concerns the inverse square law. For example, a carcinoma of the body of the uterus is to be irradiated; this organ is located approximately at the center of the pelvis, about 10 cm. from the surface in the average patient. If the source of radiation were placed 10 cm. from the patient's skin and the absorption of energy in the intervening tissue entirely disregarded, only 25 per cent of the dose delivered to the surface would reach the tumor. If the source were moved to 50 cm. from the patient, it would take twenty-five times as long to give the dose to the skin, but the tumor would receive 69 per cent of the surface radiation. This is a purely theoretical consideration, and in actual practice, the figure of 69 per cent would be considerably reduced by tissue absorption. Radium would afford an ideal source of energy for external application if it could be obtained in sufficient quantity. However, when the amount of radium ordinarily available is placed at sufficient distance from the patient to deliver an adequate depth dose, the time of application becomes so long that the method is not practical. The commonly employed "deep

therapy" x-ray unit, which operates at about 200,000 volts, can be used at distances of 50 to 80 cm. without undue prolongation of the treatment time. The amount of radiation delivered below the surface with this type of therapeutic apparatus is greater than that obtainable from the usual radium application. Radium is chiefly valuable in the treatment of readily accessible, fairly well localized growths, in which it can be used by direct application or by implantation. Frequently a combination of x-ray and radium therapy is advisable, one treatment supplementing the other.²

Roentgen rays generated at potentials considerably in excess of 200,000 volts are now available and are known as "supervoltage rays." It has been possible to produce these rays in tremendous intensities with wave lengths as short and penetrating as the gamma rays of radium. The treatment time at a distance of 100 cm. or more is relatively short. It should be emphasized that there is nothing new in the quality of supervoltage x-rays. The advocate of radium therapy becomes, unwittingly or otherwise, an advocate of supervoltage roentgen therapy, since the two types of radiation can now be made identical.

As the wave length of an x-ray beam is decreased, — that is, as the voltage and filtration are increased, — certain physical and biologic changes have been observed: there is an increase in the amount of radiation delivered below the surface (depth dose); there is a lessening of skin reaction (it takes more roentgen units to produce an erythema); the size of the portal of entry has less effect on depth dose; and there is less scattered radiation. These facts have been established beyond question.³⁻⁵ A review of the conflicting observations on the therapeutic value of supervoltage x-ray would, at present, be confusing. However, an intense source of radiant energy of a quality equivalent to the gamma rays of radium is certain to occupy a major place in the armamentarium of the radiotherapist.

The method of application of radium or roentgen rays varies in some degree with the training and experience of the radiologist. A small, accessible growth may often be successfully treated by a single intensive dose. The radiation necrosis resulting from such therapy will heal satisfactorily provided the area irradiated is not too large. If the disease is extensive or deeply situated, the so-called "divided dose" is usually employed. This consists of relatively small amounts of radiation administered daily, or perhaps at longer intervals, with an extension of the treatment series over a period of days, weeks or even months.⁶ Presumably, neoplastic cells have a slower rate of recovery from the damaging effects of radiation than nor-

mal cells, and it is on this basis that the divided dose technic has been established. The aim is to build up a total intensity that will be lethal to cancer tissue, but from which the normal structures included in the field of radiation will recover.

A reasonably accurate prognosis following radiation therapy is not only difficult but frequently impossible. The pathologist can be of considerable help, but one must still rely to a large degree on the method of trial and error. Warren⁷ states

While it may be said that, as a rule, less differentiated tumors are more radiosensitive, this is not completely correct. Indeed, our knowledge of the response of various tumors to irradiation rests largely on empirical grounds. It should be mentioned in passing that while histologic grading of malignancy is of some assistance

in estimating radiosensitivity, many tumors of the higher grades are radioresistant, and some of the lower grades radiosensitive. Even with tumors of the same histologic type there may be variation in response, and even in the most resistant types an exceptional case may respond well to radiation therapy.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 28371

PRESENTATION OF CASE

First admission. A fifty-nine-year-old Portuguese unemployed cabinet-maker was admitted to the hospital because of hematuria, followed by pain in the back and a chill.

The patient was in good health until ten days before entry, when he began to pass bright-red blood in the urine. The urine then became a persistent, uniform dark brown. Dull backache developed, about equally on both sides. The pain was unrelated to respiration and was not relieved by strapping. The day before entry, the patient had a shaking chill followed by profuse perspiration. There was no nocturia, dysuria or other urinary symptom.

Thirty years before admission, the patient had gonorrhea, characterized by an acute urethral discharge. This was cured after several months' treatment. A few years later, some bright-red blood appeared in the urine without antecedent manipulations, and the urine became dark colored. The patient took some pills, and the urine again became normal. At no time were there any symptoms of stricture. No instruments were ever passed. Nine years before entry, the patient began to have burning epigastric distress coming on just before meals and usually relieved by food. Acid and gaseous eructations were associated. An "ulcer" was demonstrated by roentgenogram, and medical treatment was instituted. After two years, the symptoms previously noted became severer, with stabbing pain, vomiting and tarry stools. Roentgenograms taken in this clinic and in another metropolitan hospital showed an active duodenal ulcer. Ultimately, subtotal gastric resection, with posterior Polya anastomosis, was performed in this hospital. The postoperative course was uneventful, and the patient remained symptom free in the four years preceding his re-entry for different complaints.

On admission, the patient appeared frail, thin and ill. The heart was of normal size, with distant sounds. The lungs were normal. There was well-defined tenderness in the left costovertebral angle, without spasm or palpable mass. The abdomen was normal except for the scar of the previous laparotomy. The prostate was one and

a half times normal size and rubbery, without nodules.

The blood pressure was 130 systolic, 80 diastolic. The temperature was 100°F., the pulse 80, and the respirations 18.

Examination of the blood showed a red-cell count of 4,400,000 with 70 per cent hemoglobin, and a white-cell count of 9600 with 69 per cent polymorphonuclears, 22 per cent small lymphocytes, 7 per cent monocytes and 2 per cent eosinophils. The blood Hinton reaction was negative. The non-protein nitrogen was 33 mg. per 100 cc. The urine showed a ++ test for albumin, with many red and white cells in the sediment.

An intravenous pyelogram showed prompt excretion of the dye. The upper calyces of the left kidney were slightly dilated, but the corresponding pelvis was not visualized. The right renal pelvis and calyces were normal. The kidney outlines were not visible. The spine showed lateral curvature and rarefaction of the bones, without evidence of metastatic lesions. There was a large filling defect in the base of the bladder suggesting an enlarged prostate, and the bladder showed trabeculation.

A second intravenous pyelogram failed to confirm a filling defect in the left pelvis. A flat roentgenogram of the abdomen showed normal kidney shadows.

Following dilatation of a stricture of the urethra, cystoscopy was performed. The bladder was markedly trabeculated, but no stones or tumor was evident. The median lobe of the prostate was hypertrophied. Urine cultures taken from each ureter grew colon bacilli, and were negative for tuberculosis on guinea-pig injection.

A left retrograde pyelogram showed definite dilatation of the upper calyces, but was otherwise unsatisfactory owing to movement of the patient. On the sixteenth hospital day, the patient was discharged, pending the report on the urine cultures.

Second admission (three weeks later). Four days after discharge from the hospital, the patient noticed recurrence of slight ache in the back and flanks. Four days later, severe pain appeared in both left and right flanks, associated with chills and two episodes of gross hematuria. The flank pain became increasingly severe. There was constant malaise.

On re-examination, the patient appeared essentially as before. Costovertebral tenderness was marked on the left and but slight on the right.

The temperature was 102°F., the pulse 90, and the respirations 25.

Laboratory data were much as before. The white-cell count was 28,400.

The day after entry, ureteral catheterization was attempted, but resistance was encountered high at the left ureter. The next day, the patient was very sensitive over the costovertebral angles, but complained of pain over the mastoid process. There were no physical signs of parotitis. The patient was given sulfathiazole, with a prompt fall

lobulated. No barium could be brought into the cavity from the gastrointestinal tract. The remnant of the stomach was displaced to the right and anteriorly. The splenic flexure of the colon was displaced downward. Smaller, irregular, air-filled spaces lay in the left midabdomen below the large cavity. The midportion of the small intes-

FIGURE 1. *Roentgenogram Showing Large Pocket of Air and Fluid beneath the Dome of the Left Diaphragm.*

in the temperature. An intravenous pyelogram showed no essential changes from earlier examinations. Roentgenograms of the cervical and dorsal spine were essentially negative. After a week and a half, the patient still complained of pain in the neck. Retrograde pyelography of the left kidney was again unsuccessful, owing to ureteral block. A rise in temperature followed the manipulation.

Roentgenograms of the gastrointestinal tract showed a large pocket of air and fluid beneath the dome of the left diaphragm, posteriorly, measuring 7 cm. in diameter (Fig. 1). The lower and medial borders of this cavity were irregularly

uneven. The urine was displaced forward slightly, on the left. On the thirty-second hospital day, an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. WILLIAM C. QUINBY*: "The urine then became a persistent, uniform dark brown." This has no specific significance except that it means that the blood was shed some time before it appeared. One does not as a rule find a patient passing urine of this type unless there has been precipitation of hemoglobin. The change to brown color has very little clinical significance.

*Clinical professor emeritus of genitourinary surgery, Harvard Medical School, chief, Urological Service, Peter Bent Brigham Hospital.

"Subtotal gastric resection, with posterior Polya anastomosis, was performed in this hospital." That is an operation, as I understand it, in which one reduces the size of the nonacid-producing part of the stomach by a resection of its terminal portion. Nothing is said about the specimen removed at that operation.

I do not know what the term "rubbery" means. It could be anything from sponge rubber to bakelite, I suppose. There were no nodules, and no suggestion that the prostate was carcinomatous.

The hemoglobin and red-cell count were not low for a person said to appear chronically ill. Evidently, the hematuria was no longer severe. The white-cell count was also not suggestive of any severe infection. The renal function seemed normal.

On intravenous pyelography, there was seen some suggestion of dilatation of the upper calyces on the left—the side on which tenderness had been elicited. The pyelogram on the right was normal. "The kidney outlines were not visible." One is interested to know why they were not, but no explanation is given. In a patient who is thin and chronically ill, it should be possible to see the outline of the kidney in a properly exposed film, unless a soft-tissue mass or gas or something of that sort obscures the renal shadow. At a second pyelography, however, the renal shadows appeared normal. At this time also, the "pyelogram failed to confirm a filling defect in the left pelvis." Does this mean that the pelvis appeared normal, or just what does it mean? We are not told.

A cystoscopy was performed; presumably, whatever stricture may have been present was easily dilated, so that the instrument could be passed and therefore had played no part in the patient's difficulties. Nothing much is said about the patient's state on this examination except that there was "hypertrophy of the median lobe." Since the prostate was found to be enlarged on re-examination, there must have been some other symptom than that of the median lobe, for it could not be felt rectally. No statement regarding the appearance of the urine appears. On the whole, I must regard the prostate as the cause of the patient's difficulties. The left retrograde pyelogram showed dilatation of the upper calyces. Here, again, we have confirmation of the first intravenous pyelogram. The cultures of the urine showed the color change in each kidney.

During the three weeks out of the hospital, the patient did badly, and had more back pain; although this was in each kidney, the examination revealed much more tenderness on the left. At this time, his poorer condition

was accentuated by a leukocytosis and fever. At a second cystoscopy, the statement is made that resistance to the passage of the catheter was met "by the left ureter." But this is again indefinite. If the catheter pass 20 or 25 cm., the normal distance being 30 cm.? We do not know. Also, neither at this nor at the previous cystoscopy was there any mention of bloody urine from either catheter. We do not know whether to assume that the hematuria was from the left or the right side or from neither.

Pain over the mastoid process is a queer complaint in this story. I should like to know whether there was any evidence of infection, or whether there was any discharge from the ear. Nothing is said about the ear. They did not x-ray the mastoid process, but they did x-ray the cervical spine, with negative results.

Two further x-ray examinations were made as an endeavor to learn more about the left kidney. The intravenous injection showed nothing new, and the retrograde route again showed a blocked ureter. Ten days later he complained of pain in the neck. I do not know what this means. At this time, the bladder was empty of the gastrointestinal tract. There was no pocket of air and fluid below the diaphragm. This was a flat roentgenogram. A flat roentgenogram showed normal kidney shadows on the x-ray films?

Dr. Larrabee performed a stricture of the ureter. The bladder was seen, but no stones or tumors were seen. The median lobe of the prostate was enlarged. Urine cultures taken from the bladder showed a few colon bacilli, and were negative for tuberculosis on guinea-pig injection. The retrograde pyelogram showed definite dilatation of the upper calyces, but was otherwise normal. Owing to movement of the patient, the retrograde pyelogram was repeated on the sixteenth hospital day, the patient was discharged, pending the report on the urine cultures.

Second admission (three weeks later). Four days after discharge from the hospital, the patient noticed recurrence of slight ache in the back and flanks. Four days later, severe pain appeared in both left and right flanks, associated with chills and two episodes of gross hematuria. The flank pain became increasingly severe. There was constant malaise.

On re-examination, the patient appeared essentially as before. Costovertebral tenderness was marked on the left and but slight on the right. The temperature was 102°F., the pulse 90, and the respirations 25.

Laboratory data were much as before. The white-cell count was 28,400.

but I think in this case it is safest to go on the evidence of the roentgenologist and at least assume that the cause of the air was not primarily bowel.

We must consider the question of the operation, a resection of the stomach four years previously. In the meantime, the patient was perfectly well. That type of resection is not made as a rule for cancer, which in a duodenal ulcer is not nearly so common, although it does occur, as an ulcer situated on the proximal side of the pylorus—namely, a gastric ulcer. Both of these areas had been removed. It is accordingly very difficult to see how this manifest abscess had anything to do with the previous operation, or how it could have any special connection with the intestine. Also, it was on the left side, bearing no relation to the septic pylephlebitis or liver abscess.

I thought first of actinomycosis (not very uncommon in the intestine) involving the colon and sigmoid, of which there is no evidence. There is no justification for assuming that the prostate contained this phenomenon.

Could this phenomenon follow a tumor of the kidney? Probably not. A tumor of the kidney, if necrotic and secondarily infected, may show no evidence, but sometimes it may have general infection, and sometimes it may contain bacillus. The area of infection seems to be of the type of a carbuncle.

FIGURE 1. Roentgenogram Showing Large Air Pocket beneath the Dome of the Left Diaphragm.

in the temperature. An intravenous pyelogram showed no essential changes from earlier examinations. Roentgenograms of the cervical and dorsal spine were essentially negative. After a week and a half, the patient still complained of pain in the neck. Retrograde pyelography of the left kidney was again unsuccessful, owing to ureteral block. A rise in temperature followed the manipulation.

Roentgenograms of the gastrointestinal tract showed a large pocket of air and fluid beneath the dome of the left diaphragm, posteriorly, measuring 7 cm. in diameter (Fig. 1). The lower and medial borders of this cavity were irregularly

to the perinephritic tissues. I am thinking especially of the so-called "renal carbuncle." This is about as near as I can come to making a diagnosis: that the patient had a renal carbuncle, which ruptured into the perinephritic tissues, and that an abscess eventually resulted in the production of gas and fluid making it visible on x-ray examination. Of course, that process takes some time, as a rule, and I am surprised, therefore, at the relatively short illness of this patient, but I do not see that this invalidates my diagnosis.

What was the matter with the mastoid process? I have not the remotest idea. What the pain in the neck was due to, I do not know. These things might very easily have been related to a general systemic infection. We are told nothing about blood cultures and given only the story that at some time or other the patient had chills. We are not given his hospital temperature chart. He was operated on, presumably for drainage of this abscess and also for a more accurate diagnosis than it was possible to make before operation.

DR. TRACY B. MALLORY: Here is the chart. The patient did have a fever all the time.

DR. QUINBY: Yes; but this is not a very striking chart.

What happened after the operation, I am not able to say, of course. We are not told that. I should guess that the patient died. I think in all probability he went on to a long suppurative process in the retroperitoneum and upper left quadrant of the abdomen. I do not know, of course, what these air pockets among the small intestines are. If these are related to the abscess, it seems to me that the condition had spread generally throughout the abdomen, and in all probability the operative outlook was bad.

DR. MALLORY: Then your first choice would be renal carbuncle?

QUINBY: Yes; if you like that term. It is a Staphylococcus aureus infection of the retroperitoneum, and may go on to suppuration.

DR. MALLORY: When I read over this story, it was performed, it also occurred to me, and I wondered at the terminology of so-called "carbuncle of the kidney" due to the staphylococcus, I should think.

DR. WILLIAM: The gas was not present all the time.

DR. MALLORY: The gas was not present all the time. There may have been secondary infection of the colon bacillus, a very frequent cause of gas in the urine. There may have been secondary infection of the colon bacillus, a very frequent cause of gas in the urine.

DR. MALLORY: I should like to ask you to consider the possibility of perforation of the colon with the catheter at the time the

*Clinical professor of medicine, Harvard Medical School, chief, Urology.

left retrograde pyelogram was done. The history states that the film was unsatisfactory because of motion. The patient was very active. Is that a possible explanation of the subdiaphragmatic abscess on the left? Does such an accident ever occur?

DR. QUINBY: I do not believe the patient suffered perforation of the ureter by the catheter. That might occur on an attempt to pass a catheter in a ureter adherent or obstructed low in its course, but when 20 cm. of catheter has been introduced, there cannot be enough force exerted to perforate a ureter unless the ureter is already necrotic. That is a possibility, but there is no evidence of it here.

DR. CHAPMAN: I thought the pain in the left neck was explainable as referred pain from diaphragmatic irritation.

DR. QUINBY: I suppose one might have pain in the mastoid process from suppuration under the diaphragm, but it must be rare.

DR. MALLORY: We have seen coronary, and I think pleural, pain referred to that area. It is reassuring to hear the urologist tell us it is almost impossible to perforate the ureter.

DR. J. DELLINGER BARNEY: I have never seen it.

DR. QUINBY: Certainly not high perforation; one cannot exert enough force.

DR. MALLORY: Have you any comment, Dr. Robbins?

DR. ROBBINS: Only that the left kidney is displaced downward by this mass, and I should say from the one retrograde pyelogram film that there is pressure on the upper margin of the pelvis.

DR. GEORGE G. SMITH: The only comment I have is that the story does not quite seem to hang together with the picture. So far as the hematuria goes, it would be a possible accompaniment of infection, but it was a rather unusual amount.

DR. QUINBY: An extrarenal mass making pressure on the renal vein will cause hematuria.

CLINICAL DIAGNOSIS

Subdiaphragmatic abscess.

DR. QUINBY'S DIAGNOSIS

Renal carbuncle of left kidney, with perforation into subdiaphragmatic region, forming abscess containing gas.

ANATOMICAL DIAGNOSIS

Hypernephroma of left kidney, containing colon-bacillus abscess.

PATHOLOGICAL DISCUSSION

DR. MALLORY: There was a great deal of difference of opinion and argument on the service

regarding the diagnosis in this case, and eventually, I believe, the patient was transferred from the Urological Service to the Surgical Service on the basis that there was enough chance that the subdiaphragmatic abscess was connected with the gastrointestinal tract to make it wiser to operate from in front rather than from behind.

He was operated on by a general surgeon, and a large tumor mass was found in the kidney area. The mass was removed with some difficulty and proved to be a hypernephroma. In its center was a large cavity in the midst of broken-down and infected tumor tissue, and the gas was all within the hypernephroma. There was no subdiaphragmatic abscess. The patient made an excellent post-operative recovery.

DR. QUINBY: He would not have if the gas had been among the loops of bowel.

CASE 28372

PRESENTATION OF CASE

First admission. A thirteen-year-old schoolboy was first admitted to the hospital because of polyuria and polydipsia.

Two weeks before entry, the patient noticed that he was forced to urinate more frequently than usual, and that he was passing large amounts of urine at each voiding. At the same time, he began to void two or three times each night. He drank at least ten glasses of water a day and seemed hungrier than usual, especially between meals. After several days, he was taken to a physician and found to have sugar in the urine. He was put on a diet and referred to the hospital.

When the patient was two years old, he had a period of "vomiting and malnutrition." At that time, a physician found sugar in the urine. This finding was not followed up. Before the onset of the evident increase in urination, the patient had occasional nocturnal enuresis. Two years before entry, he had scarlet fever, with no symptoms referable to the kidneys. A sister three years younger than the patient had scarlet fever at the age of nine, and was recognized as diabetic at fourteen. Her subsequent course bore a remarkable resemblance to that of the patient. She developed albuminuria after nine years, and retinal hemorrhages and arteriolar narrowing, a blood pressure of 160 systolic, 96 diastolic, edema and a palpable liver after ten years. The patient's father later developed diabetes, hypertension and albuminuria.

On admission, the patient appeared well developed, with evidence of some recent weight loss. The tonsils were enlarged and cryptic, with caseous inclusions. The heart was of normal

size, with a soft systolic murmur at the apex. The abdomen was normal.

The blood pressure was 100 systolic, 65 diastolic. The temperature, pulse and respirations were normal.

Examination of the urine showed 45 per cent sugar, no albumin and rare white cells in the sediment. The blood showed a red cell count of 5,000,000 with 85 per cent hemoglobin, and a white cell count of 5200 with 66 per cent polymorphonuclears. The blood Wassermann reaction was negative.

The patient was given a special diet, with insulin adjusted to free the urine of sugar. After stabilization, tonsillectomy and adenoidectomy were performed, and he was discharged to the clinic on a maintenance dose of 5 units of insulin a day.

Second admission (ten years later) An acutely inflamed appendix was removed. The patient had continued to be well during this interval, with the insulin varying from 10 to 30 units a day and diet regulation.

Third admission (two years later) The patient, aged twenty-five, had continued in satisfactory health on 40 units of insulin a day. He was readmitted to the hospital because of a cold of three days' duration. The day before reentry, he took an extra 10 units of insulin because of glycosuria, and subsequently suffered a slight insulin reaction.

On examination, the patient appeared restless, and flushed, with congestion of the conjunctivas and of the nasal mucous membranes.

The blood pressure was 128 systolic, 88 diastolic. The temperature was 100.2°F, the pulse 80, and the respirations 20.

The urine showed a trace of sugar but no albumin or abnormal sediment. The red cell count was 3,800,000 with 70 per cent hemoglobin and the white cell count 7000 with 69 per cent polymorphonuclears. The fasting blood sugar was 212 mg per 100 cc on the second hospital day. After two weeks, the patient was discharged on 45 units of protamine insulin a day.

Fourth admission (three and a half years later) The patient continued well except for several insulin reactions that necessitated reduction in daily dosage to 40 units of protamine insulin. Two months before reentry, he changed jobs to do work at irregular night hours. This occasioned difficulty in the adjustment of his meals and insulin. The urine showed sugar in several tests. At about this time, he dropped a heavy weight on his right great toe and later stubbed it. A blister formed near the nail, but soon healed. Five days before reentry, the toe was stubbed again, and became

red in several hours. The next night, the patient had a shaking chill and perspired profusely. He was admitted to the emergency ward of the hospital the next day, where it was found that he had a tender thick callus on the medial aspect of the right great toe, red streaks running up the leg, and tender inguinal lymph nodes. The callus was incised, with release of 2 cc. of pus. The leg was given local heat and elevation. The patient was transferred to the medical ward for readjustment of the insulin dosage.

Examination at this time showed blurring of the disk margin of the right fundus, with marked vascular proliferation over the disk extending into the vitreous. Many small retinal hemorrhages were present. The left eye showed a similar but less advanced picture. The chest was normal. The liver edge was displaced three fingerbreadths below the costal margin on deep respiration. The dorsalis pedis and posterior tibial arteries were palpable. The infection of the right great toe and the accompanying lymphangitis had subsided.

The blood pressure was 130 systolic, 100 diastolic. The temperature, pulse and respirations were normal.

The urine showed a +++ test for albumin in four out of five examinations, traces of sugar, and occasional red and white cells and a few fine granular casts in the sediment. The blood counts were essentially normal. The blood sugar varied from 40 to 120 mg per 100 cc. The blood cholesterol was 229 mg. per 100 cc.

A roentgenogram of the right foot showed a soft tissue swelling of the distal phalanx of the great toe, without evidence of osteomyelitis. The vessels appeared calcified.

Cultures of the urine showed *Staphylococcus aureus* and nonhemolytic streptococci. The patient was discharged sugar free on 40 units of protamine insulin a day to attend to some urgent business.

Fifth admission (four days later). The patient returned for further study. Physical examination and routine laboratory studies were as before. The phenolsulfonephthalein excretion was 60 per cent. Urine concentration tests showed ability to concentrate up to a specific gravity of 1.028. The non-protein nitrogen varied from 29 to 42 mg per 100 cc.

A flat film of the abdomen showed well outlined, slightly enlarged kidneys, with sharp shadows. There was marked calcification of the pelvic arteries. Intravenous pyelograms showed impaired secretion of the dye on the left. Retrograde pyelograms were negative.

No changes were visualized by cystoscopy. Urine from the left kidney showed an occasional white

cell, and gave a moderate growth of colon bacilli. Urine from the right kidney showed 300 red cells per high-power field, with an occasional white cell, and was sterile on culture. Following a moderate reaction to the cystoscopy, the patient was given a course of sulfathiazole. After a week, urine cultures grew nonhemolytic streptococci. After three weeks, the patient again left the hospital for business reasons.

Sixth admission (five days later). The patient returned to the hospital for continuance of studies. Physical examination and routine laboratory studies were essentially as before. Cystoscopy was again performed. The urine obtained from both kidneys was clear. That from the left kidney gave abundant growth of colon bacilli. The phenolsulfonephthalein appearance time was 3 minutes for the left kidney and 4 minutes for the right, with good concentration of the dye on each side. The patient was discharged after a week, on his usual routine.

Seventh admission (one year later). The patient continued to be fairly well, although lacking ambition and strength. He noted that his urine was "cloudy." Three days before entry, there was a sudden onset of sharp pain in the right flank, followed or accompanied by a shaking chill, with a temperature of 101°F. The pain did not radiate, and soon subsided. The night before re-entry, a similar sequence of pain, chill and fever occurred.

Physical examination was as before except for the presence of tenderness in the right flank and costovertebral angle. The pulse, temperature and respirations were normal.

The urine showed a +++ test for albumin, with 10 red cells and 25 white cells per high-power field and with occasional coarse granular casts. Abundant growth of colon bacilli was obtained on culture.

The patient was given sulfathiazole for two weeks. The urine became sterile and cleared except for a few red cells and persistent albuminuria. On discharge, the patient remained on his usual insulin.

Eighth admission (one year later). Three months after discharge, the patient gradually lost central vision in the right eye because of increasing opacity of the vitreous. He continued at work. Five months before re-entry, he began to note edema of the legs and nocturia. The blood pressure was found in the clinic to be 190 systolic, 110 diastolic. Ammonium chloride was prescribed, but was soon discontinued because of indigestion. Gradually, exertional dyspnea appeared, with puffiness of the eyes. A month before re-entry, headaches were noted, centering over the right eye. Following an upper respiratory infection,

generalized aches and pains developed. In the two weeks before re-entry, vision began to fail in the left eye. The patient suffered almost constant severe frontal headaches, vomiting and edema of the eyes and legs. At the time of entry, he was thirty years old.

Examination showed a pale, chronically ill man with edema of the face, sacrum and lower extremities. Vision was limited to finger counting at twelve inches. The heart was at the upper limits of normal size, with sounds of good quality and regular rhythm; the aortic second sound was greater than the pulmonic. The lung fields were clear. The abdomen showed questionable evidence of free fluid. There was moderate tenderness in the right costovertebral angle.

The blood pressure was 210 systolic, 130 diastolic. The temperature, pulse and respiration were normal.

The urine showed a ++++ test for albumin, a trace of sugar and a specific gravity of 1.010, with occasional red and white cells and hyaline and granular casts. The red-cell count was 3,400,000 with 11.2 gm. hemoglobin, and the white-cell count 13,200. The nonprotein nitrogen was 45 mg. and the serum protein 4.1 gm. per 100 cc. The carbon dioxide combining power was 23.4 milliequiv. and the chlorides 104.2 milliequiv. per liter. The calcium was 10.6 mg., the phosphorus 4.2 mg., and the phosphatase 4.1 Bodansky units per 100 cc.

Intravenous pyelograms showed no definite excretion of dye in the course of an hour.

The patient did poorly. There was frequent vomiting, and the peripheral edema persisted. A furuncle slowly developed on the right leg. It was poulticed at first, and later incised and drained. The patient was discharged slightly improved after five weeks.

Final admission (two days later). The patient remained in bed at home. At 2 o'clock in the morning of the day of re-entry, he had a brief generalized convulsion. He was then rational for three hours, when he became unresponsive except to painful stimuli, and had frequent generalized convulsions. He had taken the usual dose of 20 units of protamine insulin on the preceding day.

On examination, the skin was hot and dry. The eyeballs were firm and roving. The heart action was rapid and regular, with a scratchy sound heard only during systole and limited to the pulmonic area. The lungs seemed clear. The bladder was distended to two fingerbreadths above the umbilicus. Tendon reflexes were active, with bilateral Babinski plantar responses.

The blood pressure was 260 systolic, 150 diastolic. The temperature was 104°F., the pulse 140, and the respirations 35.

Examination of the urine was as before. The white-cell count was 42,000 with 97 per cent polymorphonuclears. The blood sugar was 1047 mg. per 100 cc., falling to 731 mg. in two hours, after administration of 30 units of protamine insulin and 66 units of ordinary insulin. The carbon dioxide combining power was 17 milliequiv. per liter. A lumbar puncture gave clear fluid under an initial pressure of 230 mm. of water.

Consciousness was never regained. The fever remained high. Therapy included 500 cc. of 2 per cent magnesium sulfate solution, and repeated doses of insulin. Death occurred on the second hospital day.

DIFFERENTIAL DIAGNOSIS

DR. THOMAS V. URMY: I think we all agree that this man had diabetes mellitus, and that it probably began much earlier than at the age of thirteen. He may have had it at two. At no point until the end was there any great difficulty in controlling the glycosuria. One would have to say that this was not more than a moderately severe case.

Probably the most striking feature in the whole history is the story that the younger sister and father developed very similar clinical pictures. It immediately raises the question whether or not we are encountering a definite syndrome or pathologic entity characterized by diabetes, renal lesions and vascular changes instead of a mere coincidence of separate diseases. Such a syndrome has been described in the past few years, although in what little reading I have done, I do not remember any account of family predisposition. This newly recognized disease has been called intercapillary glomerulosclerosis. Its clinical manifestations have been diabetes, hypertension, albuminuria and retinal vascular changes. The albuminuria and retinal changes have usually been rather marked, particularly the latter which are out of proportion to the appreciable length of time most of these people survive discovery of the condition. Edema is another common finding and often reaches a degree suggesting nephrosis. Thus, this patient's story can be explained by this condition, although we should possibly consider some other things.

Ordinarily, we should have to rule out chronic glomerulonephritis, with a nephrotic element terminally. It is rather difficult to do this clinically. The patient gave a history of what appears to have been a streptococcal infection at the time of

his fourth admission, when he was twenty-six and a half years old. At the same admission, it was found that he had slight hypertension, as well as some albumin and casts in the urine. The peculiar feature then was that he already had marked vascular changes in the retinas. It is difficult to believe that such changes could have progressed so far since the onset of the streptococcal infection. We also have a history consistent with recurrent urinary-tract infections. On one entry, it appears that the patient must have had pyelonephritis. Therefore, I wonder if this contributed to his evident renal failure.

Of course, hypertension is very much commoner in diabetes than in the general population. Was this, simply, hypertension developing in a patient with diabetes since an early age? Early x-ray studies reported here did show marked arteriosclerotic changes. One must also consider kidney failure developing secondary to hypertension, with later a nephrotic picture due to a possibly coincident amyloid disease.

I think, as I have said, that it is difficult to rule out completely the other possibilities, but there are certain things that make it more likely that the condition of intercapillary glomerulosclerosis was present. One is the relatively long survival—two years—after marked retinal changes were demonstrated. The serum protein was very low. Probably, there was more albuminuria than is seen in the ordinary case of chronic glomerulonephritis. Edema was more prominent, too.

Against the diagnosis is the age of the patient. I have not reviewed all the cases reported, but in a series that Newburger and Peters¹ reviewed in 1939, all patients were in older age groups. The youngest one did not develop even diabetes until after the age of forty. It seems quite unusual to have the diabetes begin so early in childhood and to have the whole course of the disease completed before the age of forty. The sex is also somewhat against this diagnosis, since the condition is described as much commoner in females than in males. The family history is, to my knowledge, unusual. However, I do not believe that these inconsistencies overbalance the points in favor of intercapillary glomerulosclerosis.

DR. ALLEN G. BRAILEY: A number of cases in childhood have been reported. I cannot give the reference, but I recall reading it recently.

DR. TRACY B. MALLORY: Dr. Beckman, you have seen a case at a comparatively early age.

DR. W. W. BECKMAN: Yes; it started in a person with diabetes from childhood. The patient, slightly over thirty, is still alive, with such severe retinal changes that he is almost completely blind.

RHUS TOXIN

To the Editor: Today, I saw a man with an urticarial type of skin eruption. His local physician, who referred him, had said that he had poison-ivy dermatitis and that, to save time, he might as well receive an injection of rhus toxin. The physician also stated that the toxin was a specific for poison-ivy dermatitis and that, even if he did not have this type of eruption, the injection would do him no harm.

I believe this false sense of security prevails among the medical profession at large, owing to the enthusiasm of detail men from the various drug houses. If this physician were to attend any large dermatologic clinic, practice dermatology or give injections of this antigen to a large series of patients, I am sure that he would be convinced that his statement was not true. These injections do a great deal of harm in many cases.

For example, within the past week I have seen at least ten bad results from them. One patient received an injection in the arm, with a resulting erythema and edema that was very disabling and painful. Another patient received a series of injections, and six days after the last, when the dermatitis had healed, was seized with a severe urticarial reaction that persisted for a considerable length of time. Still another patient had a widespread attack of what was formerly called "chronic eczema" but is now labeled "neurodermatitis." It came on three weeks after a series of injections with rhus antigen. This neurodermatitis is probably the beginning of a disabling dermatitis, which will prevent the patient, a student nurse, from completing her training.

I have also seen cases of exfoliative dermatitis occurring after this type of injection.

Rhus toxin cannot be given without the ever-present danger of a later allergic reaction. It should be used with caution. I have found it to be of little value in therapy, and its use as a prophylactic is still being disputed by many dermatologists.

REPORT OF MEETING

BOSTON CITY HOSPITAL

The second in the series of lectures sponsored by the Boston City Hospital House Officers' Association for the preparation of those entering the armed forces was held at the hospital on May 7, with Dr. Henry Marble discussing "Traumatic Surgery."

Two of the most trying problems of the World War I have been minimized by the routine blood typing of all men and the administration of tetanus toxoid for active immunization.

The first-aid treatment of fractures of the extremities has not changed much. Some type of Thomas splint for all fractures between the ankle and hip or of the Murray-Jones splint for those between the wrist and shoulder is still the immobilization of choice. The only things that need be emphasized are the use of adequate padding and the keeping on of the splint for the shortest possible period. In compound wounds, iodine is painted around the skin edges only, and a dry sterile dressing applied. Most, if not all, men in combat will be supplied with some sulfonamide powder, at least 1 gm. of which should be inserted in such wounds. The patient should be treated for shock, with double the usual amounts of morphine, warmth and adequate splinting, and for incipient sepsis with sulfonamide orally.

The first-aid station or field hospital is essentially a "triage station," where the patients are segregated into

shock cases, chest wounds, abdominal wounds, minor wounds and so forth. An experienced man does this important phase of the work. The order of operations is generally abdominal, chest, head and extremities. All cases of actual or incipient shock are treated in special rooms with plasma or blood, as well as the usual supportive measures.

Dr. Marble discussed particularly wounds of the extremities, which are usually not considered emergencies. Some amputations, which are performed at the field hospital, are of the guillotine type. It is definitely established that the use of the sulfonamides at the first-aid station lengthens to as long as seventy-two hours the period in which a wound may be treated as fresh and a primary débridement done. Anesthesia is a difficult problem largely because of transportation limitations. Ether is bulky and explosive, and nitrous oxide is also bulky. Spinal anesthesia is fine for the lower extremities if available, and Pentothal is satisfactory in the arm. Both, but particularly the latter, require what probably is not generally available—an experienced and competent anesthetist. This all indicates that chloroform, which is infinitely easier to transport, will be in wide use. Its dangers, furthermore, are probably overemphasized, according to Dr. Marble.

The first consideration, of course, is an evaluation of the case for shock and continuance of its treatment. Compound wounds are débrided and copiously irrigated. But, here again, what is written in the books may often not materialize because of lack of the "sharp knife and unlimited quantities of sterile fluid." The best must be done, often with inferior equipment. Again the wound is dusted with one of the sulfonamides, which is also given by mouth. The wounds are left open, despite the fact that they are now being closed by some men even in the presence of gas bacilli when the sulfonamides are used. This is not yet practical on a large scale. The number and virulence of gas bacilli vary remarkably with the locality.

The fracture itself at the field hospital is best returned to its traction splint, possibly with skin traction instead of the ankle or wrist hitch. Further transportation is in the offing, and the use of plaster-of-Paris casts has not proved practical when the state of the wound is questionable, and when constant observation during transport is not possible. When good results have been reported with this method, the wounds have been fresh, and there has been no further transportation. If adhesive skin traction has been instituted, the patient is always ready for transfer to bed traction. In Dr. Marble's opinion, closure of wounds is permissible only when they have been proved bacteriologically to be reasonably free of at least serious pathogenic organisms. Such facilities are usually found only at base hospitals farther back. Plating of fractures may be carried out in the rare event that the equipment is at hand, but even then the wound should be left open.

Whenever severed nerves are encountered, an attempt should be made at a suture of some sort. It has been demonstrated that these structures do almost as well in septic as in clean wounds, and any identifying material on the nerve ends facilitates secondary repair of the nerve. For this reason, some means of identification should always be introduced, for improperly treated nerve injuries result in the severest sequelae.

Tendons, on the other hand, have notoriously poor results in septic areas. But this should not prevent one from attempting suture, for nothing is lost and the ends may be kept somewhere near approximation for secondary repair. In any event, Dr. Marble is not yet ready to advocate primary closure of the superficial tissues in compound wounds of any kind.

NUMBER 12

THE PHYSICIAN'S STATUS IN CHILD-GUIDANCE WORK*

PHILIP SOLOMON, M.D.†

BOSTON

PROBABLY no field of human endeavor is in such a state of confusion as that of child guidance, which had scarcely been heard of fifty years ago. Today, everybody wants to guide the child. The discovery that "the child" was a fallow field for exploitation aroused enthusiasts from many walks of life. Teachers, social workers, district nurses, clinical psychologists, lay psychoanalysts, and religious leaders, have laid claim to the ability to solve the problems of childhood. The United States Government itself has recognized the importance of this movement and has gone to considerable pains to organize a White House conference on the child, which has taken place in Washington once in each of the last four decades. The medical profession has not stood idly by during this time. Having long ago recognized the specialized nature of the physical problems of childhood by the creation of pediatrics, physicians now see in the mental, emotional and behavioral problems of childhood the need for a special branch of psychiatry.

Child psychiatry is one of the youngest of the medical specialties. Most of the work done in this field has been descriptive, explanatory and theoretical. The present status of child psychiatry may be likened to that of general psychiatry before Kraepelin, since there is not even the beginning of agreement regarding the proper classification of the various problems involved. Diagnosis and treatment are still more of an art than a science, and much of the work done is strictly on an empirical basis. Here and there, one sees attempts to introduce scientific methods of observation and controlled experimentation, but these researches stand out conspicuously in the literature against the background of untested theory, unverified speculation and thoroughly prejudiced points of view.

Under these circumstances, one may well ask whether a physician is necessary in child-guidance work. If such work is largely spiritual, perhaps a minister would be better qualified, if educational, a teacher, and if sociologic, a social worker or recreational leader. Surely, many problems of thumb sucking and bed wetting can be dealt with adequately by the district nurse, and many truants and delinquents can be handled by the truant officer, policeman or probation officer. What are the special abilities of the physician in these matters, and does the need for such abilities arise sufficiently often to warrant the presence of a physician in a child guidance clinic?

PROCEDURE

In an attempt to answer these questions, the records of 100 consecutive cases seen at the Habit Clinic for Child Guidance, Boston, were studied.‡ The patients were all seen within a period of approximately two years. They represent a fair cross section of the cases seen in the clinic and in others dealing with children in this age group. The ages ranged from one to eleven years, with an average of six years. There were 73 boys and 27 girls. The problems presented included the usual ones of habit reactions (poor eating, sleeping and elimination, and disobedience), predelinquency (stealing, lying and truancy), personality peculiarities (shyness, boldness, cruelty and neurotic complaints), educational difficulties (poor school progress and specific defects), tics, mannerisms and speech disturbances. The approach in each case was threefold: physical, intellectual and emotional.

Since the details have been described at length elsewhere,§ it will suffice to point out that each child was examined physically by either the fam-

‡When two or more children in the same family were patients only the first child referred was included in this study so that the 100 cases represent a hundred different families.

§Thom, D. A. *Habit Clinics for Child Guidance*. 97 pp. Washington: Children's Bureau, United States Department of Labor, 1939.

ily physician or a physician in the outpatient department of a hospital situated conveniently near the family. In some cases, the psychiatrist did part or all of the physical examination himself, or requested that a special examination, including blood and urine tests, lumbar puncture, x-ray films and electroencephalograms, be done elsewhere. The clinic psychologist administered a battery of intelligence tests to each child. The psychiatric social worker studied the home, school and neighborhood, and brought back the pertinent sociologic data. The psychiatrist evaluated this material and, in addition, attempted to gain knowledge of the child's emotional life through interviews with the child and parents. All this represents the usual procedure in child-guidance clinics.

In this study, the cases were classified in two ways. Each case in the first classification was put in one of the following groups:

Group A. Cases in which the problem was considered to be due primarily to organic disease in the child.

Group B. Cases in which the problem was considered to be due in part to organic disease in the child.

Group C. Cases in which organic conditions were found in the child, but in which these were incidental and not related to the basic problem.

Group D. Cases in which organic factors in the child played no part but in which incidental medical advice was given to other members of the family.

Group E. Cases in which organic factors in the child and medical advice played no part.

In the second classification, each case was put into one of the following classes:

Class H. Cases in which only a knowledge of the proper methods of child management was necessary.

Class M. Cases in which the knowledge and training of a physician were required.

Class Q. Cases in which only the knowledge and training of a psychologist were necessary.

Class P. Cases in which the knowledge and training of a psychiatrist were essential.

Examples of the various groups and classes are as follows:

CASE REPORTS

GROUP A, CLASS M.

A. C. (Case 2866), a 9-year-old boy, was referred to the clinic by his mother, at the suggestion of the Community Health Association, because of bed-wetting. A routine physical examination was negative, psychologic examination revealed good normal intelligence, and psychiatric interviews revealed no emotional data of great consequence.

It was believed that the patient's enuresis was due to faulty training or insufficient motivation. The usual enuresis regime was instituted, and the patient was given a great deal of suggestion and encouragement. After 6 months of treatment, however, there was no improvement in spite of what seemed to be excellent co-operation on the part of both the patient and the mother. The child was therefore referred to a genitourinary surgeon for special investigation of the genitourinary tract. It was found that the patient's urinating was characterized by a weak stream and dribbling. A urethrogram showed a definite narrowing of the anterior portion of the urethra, apparently a congenital stricture. The patient was dilated, by bougies of increasing size, and his symptoms rapidly improved.

GROUP A, CLASS P.

F. B. (Case 2994), a 7½-year-old girl, was referred to the clinic by the Boston City Hospital. The child had been taken to the hospital by the parents because of increasingly severe behavior problems, which had finally caused her to be expelled from school. She was mischievous, defiant, unruly, extremely hyperactive, distractible and impulsive, and much of her behavior was bizarre. There was a past history of convulsions, dating from the age of 1½ years. Recently, there had been a few minor seizures of a petit mal nature. A 3-year-old brother had convulsions regularly. Because of the severe degree of the patient's behavior problem, an attempt was first made to have her institutionalized. This was not immediately successful.

An electroencephalogram showed abnormal waves, some of which were of the wave-and-spike pattern characteristic of petit mal. Apparently, the child was having these abnormalities disturbing the function of the cortex almost constantly, although not to a sufficiently severe degree to produce clinical seizures. She was started on dilantin sodium, and the dose was increased until she was taking 0.2 gm. a day. A remarkable change occurred in her behavior almost immediately. The child became "a different girl." Her misbehavior stopped, and she apparently quieted down and became co-operative and obedient. She seemed to be in every way a perfectly normal child. Under the medication, this improvement continued, except for two intervals when the medicine was stopped—once because the parents ran out of it, and once when the child had a cold. On both occasions, the previous difficult behavior occurred. Because of the improvement, the child was allowed to go back to school on trial, and she made an excellent adjustment there. A check-up of the electroencephalogram later revealed normal brain waves.

GROUP B, CLASS M.

N. W. (Case 2689), a 5-year-old girl, was referred to the clinic by her mother because of night terrors and because she was generally tense and high strung. It was found that the mother had been unusually severe in her disciplining of the child. The child had been given glasses for a strabismus. However, one of the lenses had become rotated following a fall. Consequently, the strabismus had become worse, and there was a noticeable increase in the child's "nervousness." The glasses were immediately changed, and the mother was urged to modify her management. The child soon responded with improved general behavior and the disappearance of the night terrors.

GROUP B, CLASS P.

T. D. (Case 2837), an 8-year-old boy, was referred to the clinic by his mother because of unwillingness to go to school, crying spells, irritability and "general maladjustment." The parents were well educated, tense and over-

serious in their attitude toward their only child. Recently, the child had begun to bite his fingernails, twitch his face, screw his mouth about, pull at his eyes, hunch his shoulders, and "generally wiggle." It was found that he was in good physical health, but was still taking thyroid tablets, which had been prescribed for him when he was 4 years old because of "lack of pep." On psychologic examination the patient had an intelligence quotient of 143. The thyroid medication was stopped, and much work was done with the parents and the child in attempts to alter their attitudes. As time went on, the patient's symptoms gradually dwindled, and the parents gained confidence in the clinic. They soon began to lean on us for advice in all the minute details of the child's life. Eventually there was a great improvement in the entire family situation.

GROUP C, CLASS H

H H (Case 2776), a 2½ year-old boy, was referred to the clinic because of feeding difficulties and bed wetting. The patient was an only child, and the mother was erratic and inefficient in her daily schedule with the child. She was given routine advice regarding the child's eating and elimination, and many suggestions were made to her about the improvement of her schedule. The patient was entered in an all day nursery school, and at the mother's request the psychiatrist examined him physically and filled in the blank required by the nursery school.

GROUP C, CLASS P

R B (Case 2781), an 8½ year old boy, was referred to the clinic by his teacher because of poor work in the class room. The mother added that the boy bit his nails and sucked his thumb.

The patient was the only child of a middle aged couple. The mother had a great many interests and was not concerned about her maternal duties. It was difficult to get her to take the child's problem seriously or to follow clinic recommendations. The patient was found to be physically well and of superior intelligence. It was believed that his work habits were poor, and that he was a fundamentally unhappy boy. In the course of a year's contact with the case, the mother's attitudes were modified but little. The father could not be seen, but after repeated interviews, the child was given some insight into his mother's make-up. Through the Cub Scouts, summer camp, tutoring in reading and direct psychotherapy, the boy began to make a better adjustment to his life situation.

GROUP D, CLASS M

C C (Case 2758), a 6½ year old boy, was referred to the clinic because of soiling. The child was the second of six children living in an extremely dirty, poverty stricken and badly managed home. The mother was unintelligent, and the father was being treated for pulmonary tuberculosis. It was found that the patient was sleeping on a small cot with the father. The psychologist found the patient to have superior intelligence. It was believed that the soiling was a reflection of the unsatisfactory home conditions. The child was placed in a preventorium for children suspected of tuberculosis. While he was there, his problem rapidly disappeared. Arrangements were made for the father to resume proper treatment for his own tuberculosis, since he had allowed his pneumothorax to lapse.

GROUP D, CLASS P

M W (Case 1561), a 10 year old boy, had been a patient at the clinic at the age of 3, when he was an eating problem and responded readily to routine advice. Seven years later, his mother brought him back because she believed

that he had an "inferiority complex." She also complained that he was disobedient and unruly. It was found that most of the child's difficulties were a reflection of the mother's unstable and neurotic temperament. Work with this case covered several years, during which direct treatment was given to the mother, particularly during a period of depression that followed a pelvic operation. Since the patient entered adolescence at this time, a great deal of work had to be done to interpret the changes in the child to the mother and to the patient himself. The father was seen several times, and his assistance was solicited in helping the mother in her problems and in taking over part of the responsibility for the patient's difficulties. In the course of time, a much better relation was set up in the home, and the patient's adjustment to the outside world, and to himself, was greatly benefited.

GROUP E, CLASS H

T W (Case 2671), a 2½ year old boy, was referred to the clinic for sucking his lower lip persistently. It was found that the mother was an extremely emotional, irritable and unstable person who kept the home in a constant state of tension by scolding, nagging and spanking. The mother failed to co-operate with the clinic. She did not keep appointments, she would not accept a nursery school placement for the child, and it was not possible to get the father to come to the clinic. Efforts to reeducate the mother in her methods of managing the child were there fore unsuccessful, and it was not possible to work with the mother in her own problem.

GROUP E, CLASS Q

R G (Case 2648), a 5 year-old girl, was referred to the clinic by the mother because of the problem of school placement. The child had attended kindergarten for 27 weeks during the previous year, having been absent several times because of illness. The child was under age for entering the first grade, and the school made a ruling that only children who had attended kindergarten for 30 weeks should enter the first grade. The mother believed that the child was bright, but did not want her to go ahead with first grade work unless she were really ready for it. On the Stanford-Binet test, when the patient was 5 years old, she scored a mental age of 7 years, 2 months, giving her an I Q of 143. The child was sturdy, well poised, friendly, responsive and well mannered. She worked efficiently and rapidly at the test procedures. On the Goodenough drawing test, Merrill-Palmer scale and mare and foal test, her results were comparable to those on the Stanford-Binet. The psychologist believed that the child showed exceptionally well developed mentality, with superior personality traits and work habits. It was recommended that the child be allowed to enter the first grade. The clinic recommendations were referred to the school committee by the school principal, and the child was accepted in the first grade. She subsequently made an excellent adjustment, and her teacher stated that she was very bright. At the end of the year, the patient was promoted in spite of the fact that she had missed a good deal of attendance because of scarlet fever, measles and whooping cough.

GROUP E, CLASS P

R H (Case 3105), a 3-year old boy, was referred to the clinic by the mother at the advice of a psychoanalyst who had been treating the mother for 5 years. The complaints were unmanageable behavior, temper tantrums, nervousness and biting of the fingernails. There was a strong family history of mental disease. The mother had had several psychotic episodes, a maternal great aunt had also

been psychotic, the maternal grandmother had been psychotic in her youth, a maternal uncle was considered mentally abnormal, and a paternal uncle had had several psychotic episodes.

The child was found to be in good physical health and to have superior intelligence on psychologic tests. Observations during clinic attendance indicated that the child was wilful and largely untrained. However, he responded well to friendly management. Treatment of this child involved for the most part education of the mother in proper methods of child training. This was a rather difficult matter, since the mother's mental status was still far from normal. During the work with the case, the mother remarked that she was still having visual hallucinations, although these did not seem to influence her behavior. Another source of difficulty came from marital discord between the parents. The father was interviewed, and through the intervention of the clinic, the parents arranged matters between themselves in such a way that the child was spared any of the consequences of their quarrels. As time went on, the patient improved, although he continued to have temper tantrums occasionally. Finally, temper tantrums also disappeared, and the mother believed that the patient was behaving quite normally. Her methods with the boy had been entirely reorganized, but her own mental condition was still far from normal. She was urged to continue to see a psychiatrist for her own mental health.

RESULTS

Table 1 shows the distribution of cases according to class, group, and results. Since the

number of cases studied is 100, the various totals are percentages.

The 20 cases in Group A are of special interest. Ten of these children presented "organic behavior" or "postencephalitic behavior" problems. In only 2 was there a history of encephalitis. In 1, a birth injury was held responsible for the brain damage, and in 7 the central-nervous-system defect was considered to be innate, perhaps hereditarily acquired. In 9 of this group, the diagnosis was substantiated by electroencephalograms taken at the Boston City Hospital through the kindness of Dr. Fred-eric A. Gibbs.

The remaining 10 children in Group A are also of interest. Five were boys, with persistent enu- resis, in whom routine treatment was of no avail.

These children were studied by Dr. M. Leopold Brodny at the Beth Israel Hospital, a new x-ray technic for visualization of the genitourinary tract being used. Urethrography in each of these cases revealed an abnormality that was amenable to surgical approach. Two had a pin-point urethral meatus, and 3 had a urethral stricture farther back. All 5 had marked dilatation of the urethra be- hind the stricture. The other 5 children in Group A had the following conditions: a birth injury; defective vision, and deafness in one ear; word deafness; chorea; and an old depressed skull frac- ture.

It is noteworthy that all the children in Group A were improved. Treatment in the organic be- havior problems was in part pharmacologic, dilantin sodium or amphetamine (Benzedrine) sul- fate, or both, being administered in 7 cases. Surgery was resorted to in the 5 enuretic children. Corre- ctive glasses were obtained for the child with poor vision. Neurosurgery in the child with the old depressed skull fracture was contemplated but was postponed following both electroencephalography and pneumoencephalography. This patient, whose presenting problem was somnambulance, did well on phenobarbital and a program providing in- creased rest. The child with word deafness was given special educational attention. All the chil- dren were also treated by modifications in their environment, to allow them to adjust themselves better in spite of their handicaps.

Of the 20 cases in Group A, the 5 children with genitourinary abnormalities were placed in Class M, since they certainly needed the attention of a physician. The other 15 were placed in Class P, since each case required psychiatric treatment. It should be said that the term "psychiatric" includes "neurologic." (I emphatically agree with the Examining Board for Certification in Neu- rology and Psychiatry that every psychiatrist should be a well-trained neurologist. The material pre- sented in this paper demonstrates how necessary this is in the field of child psychiatry.)

In the 9 cases in Group B, although the chief cause of the child's difficulties was regarded as an emotional one arising from environmental rela- tions, organic disease played a significant contribu- tory role. Three of these children were put in Class M, since it was believed that a competent pediatrician could have taken care of their prob- lems adequately. One had chronically infected ton- sils, for which an operation was arranged. One was developing strabismus because a lens in her glasses had become rotated following a fall. One had "worms," for which the mother was using an ineffectual proprietary medicine obtained on the advice of a druggist; proper treatment was

instituted. The other 6 children were placed in Class P, since the emotional problems involved were severe enough to require prolonged psychiatric therapy. The organic conditions were as follows: harelip (a reoperation was arranged), instability produced by prolonged thyroid therapy recommended four years previously by the family physician (the medication was omitted following consultation with the physician), a series of minor illnesses in a child who was being badly pampered by the parents, severe eczema, poor motor coordination on a congenital basis, and flat feet (an orthopedist was substituted for a podiatrist). All the children in Group B improved.

There were 20 children in Group C, in which medical advice was given for organic conditions not related to the child's problem. Five of these were placed in Class H, since the problems involved simple readjustment of the child's routine. The medical situations concerned questions of proper daily schedules, for the most part. Four of these 5 children were three years of age or younger. Fourteen were in Class P, since they needed psychiatric care, and 1 was in Class Q. Advice in these cases was given on the following medical matters: keloid, congenital nystagmus, abscess on the buttock, positive blood Wassermann reaction (3 patients), pertussis vaccination, worms, posture abdominal pain (2 patients), constipation, chicken pox, positive tuberculin reaction and polydipsia. There was improvement in all cases.

Incidental medical advice was given to relatives of 6 children in Group D. This was in the form of a discussion with the parents of their own medical problems. In each case, the parent was referred back to his own physician, and reasons were offered in favor of the treatment contemplated or already in progress. The effect was therefore one of added authority and reassurance. The conditions were as follows: pulmonary tuberculosis in a father who had omitted his pneumothorax refills, anemia, alcoholism, multiple sclerosis, fibroids of the uterus, and severe neurosis. Two children in this group were unimproved. One was the child whose mother had the neurosis, and the other the child whose mother had the anemia. In neither case did the parents cooperate with the clinic.

The remaining 45 children were in Group E, in which no organic conditions or medical advice played a part. None of these children, therefore, were in Class M. The largest number of unimproved cases (8) fell in this group.

Of the total 100 children, 19 were in Class H. The problems in these children could have been adequately handled by a district nurse, a nursery school teacher or anyone well versed in the proper methods of child management. Neither a phy-

sician, a psychologist nor a psychiatrist proved necessary, except to rule out abnormalities in their special fields.

There were 9 cases in Class M, in which the knowledge and training of a physician were necessary in the treatment. In 5 of these (the enuretic children in Group A), the referral of the child by a nonmedical "child guidance expert" to an average physician for a check up would not have elicited the organic lesion found. Many pediatricians, however, would be in a position to do justice not only to all the children in this class but also to all those in Class H.

Class Q contained only 4 children, 2 of whom were doing poorly in school in spite of normal intelligence. It was found that both were "non-readers," and remedial reading instruction was arranged for them. One five-year-old child was too young to be admitted to the first grade in her community, and yet the mother believed she was extremely bright and could easily do the work. The psychologist found that her mental age was over seven—an intelligence quotient of 143. The school committee accepted a recommendation that the child be admitted to the first grade, and she subsequently did very well. The fourth child in this group proved to be feeble minded, and institutional care, although recommended, was not accepted by the parents. In all 4 cases, the services of the psychologist were both necessary and sufficient. Of course, in many more of the total group of patients, the psychologist contributed information of considerable value, but in all these cases, other services were necessary.

The large number of children in Class P (68) was surprising. Of course, the cases were necessarily judged in a rather arbitrary way. It may well be that someone else going over these records might not believe that all these children needed the ministrations of a psychiatrist. Nurses, psychologists and nonpsychiatric medical men could probably have done a satisfactory piece of work with many of these children. However, so far as they were able to show insight into the emotional causes for the child's problems, both in the child and in the parents, and were able to institute proper therapeutic measures for their relief, such persons would be acting the role of a psychiatrist. Certainly, many of these problems can be seen through by well directed common sense. However, treatment by a psychiatrist offered the best chance for solution of the fundamental problems in these 68 cases, and in some, treatment by anyone other than a psychiatrist would probably have been grossly inadequate.

It should be added that the average psychiatrist sees very few children and might therefore be

quite unprepared to administer the kind of psychiatric care that these children required. In fact, without special training in child psychiatry, many psychiatrists would be in a worse position for helping this group of children along emotional lines than some psychologists and pediatricians. In addition, the average psychiatrist has lost touch with the organic pediatric problems in children, so that although he is a physician, he would not be able to do justice to the children in Class M, discussed above. The child psychiatrist, however, can contend not only with the problems in Class P but also with those of Class M and Class H.

It will be noted that 10 cases were unimproved. In none of these was there occasion to give medical advice to the child. In 2, as noted above, the mothers were given incidental medical advice; in 8, failure may be attributed to lack of co-operation on the part of the parents or to inability to secure this co-operation. In 2 of the unimproved cases, failure was due to the inherent nature of the child's problem.

DISCUSSION

The question regarding the role of a physician in a child-guidance clinic may be answered by a reference to the statistical data. In 20 per cent of the cases, the child's problem was due primarily to organic disease. In an additional 9 per cent, the problem was due in part to organic disease. In 20 per cent, incidental medical advice was given to the child, and in 6 per cent to other members of the family. A total of 55 per cent of the cases (Groups A, B, C and D), therefore, required medical care.

The question naturally arises whether medical care could be furnished in child-guidance clinics in which there is no physician in attendance by the practice of referring each child to an outside physician for a routine physical check-up. In a number of clinics directed by "clinical psychologists" or other nonmedical persons, this practice is followed. The results, however, depend largely on the interest and thoroughness of the outside physicians. Our own experience with "routine physical check-ups" indicates that examinations are sometimes done rapidly, incompletely and without any particular interest in the possible special examinations or laboratory data that might throw light on the etiology of the child's behavior problem. In clinics where one or two outside physicians are relied on for this type of work, such objections may not apply, and the arrangement may work out very satisfactorily. In clinics where the director is a physician, however, children have the advantage of being seen periodically by one who will keep the possibility of organic disease constantly in mind.

When one considers that, in 29 per cent of these

cases, organic disease played an important part in the etiology of the behavior problem and that medical advice was given in an additional 26 per cent, it seems fair to say that a physician should be closely associated with every child-guidance organization and, preferably, should be an integral part of it.

Should the physician be a general practitioner, pediatrician or psychiatrist? Nineteen per cent of the patients (those in Class H) could have been treated adequately by anyone familiar with proper methods of child management; district nurses, social workers, schoolteachers and even helpful neighbors frequently do a good job with this type of case. Nine per cent (the children in Class M) needed nonpsychiatric medical care. In 5 per cent, it was believed that a pediatrician would be likelier to do justice to the case than a general practitioner. In part of the 19 per cent of Class H, the same opinion applies. Four per cent of the patients (those in class Q) specifically required psychologic services. The psychologist, of course, contributed information of value in many other cases, and if negative or corroborative data are included, it is fair to say that the psychologist was helpful in every case. It should be added that some psychologists are thoroughly capable of properly handling the cases in Class H and the majority of cases in Class P. Sixty-eight per cent of the patients (Class P) needed specialized psychiatric care. The interpretation of this type of care has been discussed above. A psychiatrist trained in

child-guidance work is also capable of doing justice to the cases in Class H and Class M.

A summary of the statistical data as they might be applied to an appraisal of various workers in their ability to handle the problems of a child-guidance clinic is presented in Table 2. Many of these figures are, of course, rough estimates. It is assumed that each worker is highly skilled

in his field. It may be seen that skilled lay workers could manage all the cases in Class H and 10 of those in Class P, making a total of 29 per cent that could be properly managed. This is probably accurate to within 5 per cent. When the lay worker uses a routine medical check up, the total of cases properly managed is raised to 33 per cent, since 4 of the cases in Class M are added. Similarly, the general practitioner, pediatrician, psychiatrist, psychologist and child psychiatrist are appraised. According to this estimate, child guidance clinics run by psychologists with assisting medical men but without psychiatrists will adequately provide for about three fourths of the patients seen at the clinic. To do justice to all the problems that may arise, both a psychologist and a child psychiatrist should be part of the clinic.

No attempt has been made to appraise the value of the psychiatric social worker in the child guidance clinic. It may be said quite categorically that such a clinic could not function without a social worker. But it is difficult to estimate how essential the work done by the psychiatric social worker in the investigation of the home, school and neighborhood was to the proper management of these 100 cases. In private work, the psychiatrist or clinical psychologist is frequently able to gather the social data himself, although this is time con-

suming and often less thorough than the study made by a psychiatric social worker.

SUMMARY

In an attempt to evaluate the proper status of the physician in child guidance work, a study was made of 100 consecutive cases seen at a child guidance clinic. The cases were classified according to the part played by organic disease in the etiology of the child's problem, and according to the type of knowledge (lay, medical, psychological or psychiatric) needed in the proper management of the case.

In 29 per cent of the cases, organic disease played a major part in the etiology of the child's problem, and medical advice was given in an additional 26 per cent. Nineteen per cent of the cases could have been treated adequately by anyone familiar with proper methods of child management, 9 per cent needed nonpsychiatric medical care, 4 per cent needed the attention of a psychologist, and 68 per cent needed treatment by a psychiatrist.

A physician should be closely associated with every child guidance clinic and, preferably, should be an integral part of such a clinic. It is desirable that the physician should be a psychiatrist, specifically trained in the management of the problems of childhood.

OBSERVATIONS CONCERNING PULMONARY FIBROSIS IN RAYNAUD'S DISEASE*

Report of Two Additional Cases

HARRY LINENTHAL, MD†

BOSTON

THREE cases of pulmonary fibrosis in patients who were suffering with Raynaud's disease were reported recently.¹ The histories were uniform. They all started with typical manifestations of Raynaud's phenomena, and after several years, nutritional changes of the skin began to manifest themselves with the development of scleroderma. Some time later, the patients began to complain of dyspnea on exertion. Roentgenologic examinations showed some evidence of fibrosis at the bases of the lungs. All 3 patients died within three or four years after the onset of the dyspnea. One patient had an intercurrent infection, which was the immediate cause of death.

Because these patients were suffering from vascular disease and because of the absence of any

recognizable factors that could explain the etiology of the pulmonary fibrosis, it was believed that there was a direct relation between the pulmonary condition and the coexistent Raynaud's disease. Therefore, Raynaud's disease can be considered to affect not only the small arteries of the extremities but also the small arteries of the lungs and possibly of other organs of the body. Since the above report, 2 additional cases have been observed. In one of these, now under observation, studies of the lung and pulmonary dynamics have been carried out. In the other, post mortem examination showed extensive pulmonary fibrosis secondary to vascular changes in the lungs.

CASE REPORTS

CASE 1. Mrs. F. J. W., a 30-year-old woman, was first seen in 1932. The past history was not significant except for frequent attacks of tonsillitis and joint pains, for which several infected teeth had been extracted. The presenting

*Presented in abstract at a section meeting of the American College of Physicians on April 22, 1941.

†Professor of clinical medicine, Tufts College Medical School; physician in chief, Beth Israel Hospital.

symptom was related to circulatory disturbances of the hands of 6 months' duration. On exposure to cold or when the patient was emotionally disturbed, the fingers of both hands assumed a deathlike pallor, became cyanosed and later developed a hyperemia, with marked paresthesia of the finger tips. She also noticed from time to time a transient blotchy hyperemia of the chest.

About a year later, the patient developed all over her body a diffuse recurrent urticaria, which had no apparent relation to her environment or food.

The patient was not seen again until November, 1940, when she stated that she had been treated for a number of months with elimination diets, without any improvement of the urticaria. Later, a tonsillectomy was performed, without improvement of either the urticaria or the Raynaud's disease. In 1935, the patient had begun to experience shortness of breath on exertion. In 1939, she had had an acute pulmonary infection, which had left her with a troublesome cough and with greatly increased dyspnea.

The Raynaud's disease had grown progressively worse. The hands and fingers showed a permanent purplish cyanosis, which became more marked on exposure to cold or excitement. The patient had well-developed scleroderma of the hands and face. She was unable to open her mouth freely. The skin on the face felt tightened, and the nose had become narrowed and sharper in outline. The tips of the index and middle fingers of the right hand showed small superficial ulcerations. She had lost 15 pounds in the last few years. Her catamenia had been scanty and irregular for a few years.

The heart was not enlarged, and the rhythm was regular, with a rate of 90. Electrocardiographic tracings did not show any significant changes. The blood pressure was 130/70. The lungs showed diminished resonance, with increased fremitus in both bases and with rales after coughing. The red-cell count was 5,900,000, with a hemoglobin of 90 per cent, and the white-cell count was 13,400; the differential count was not significant.

A roentgenogram of the chest (Fig. 1) in April, 1941, showed slight clouding at the upper peripheral portions of the chest in the first interspaces anteriorly on both sides. There was slight diminished radiance at the left base, with flattening and limitation of the excursions of the left side of the diaphragm. In other words, the roentgenogram of the lungs did not show sufficient changes to account for the extreme dyspnea and cyanosis.

In July and again in September, Dr. Mark D. Altschule carried out studies on the patient's pulmonary dynamics, which have been described briefly elsewhere.² The following observations are particularly pertinent: total lung volume, 2495 cc.; vital capacity, 795 cc.; complemental air, 595 cc.; reserve air, 200 cc.; midcapacity, 1900 cc.; and residual air, 1700 cc.

The total lung volume was about half normal. The complemental air was about 25 per cent normal, indicating very marked impairment of distensibility owing to abnormal rigidity of the lungs. The reserve air was about a quarter normal and likewise indicated considerable loss of elasticity of the lungs (again because of fibrosis). The loss of elasticity caused the intrapleural pressure to be less negative than normal, and the respiration was further embarrassed.

Failure of the lungs to expand and to relax properly keeps the tidal air low (in this case, 315 to 373 cc.) and makes washing out of the residual air (the air that cannot be expelled from the lungs) difficult. To prevent or minimize arterial anoxemia and retention of carbon dioxide, increased respiratory activity is necessary. The

patient exhibited this increase (respiratory rate, 23 to 26 per minute, and respiratory volume, 8200 to 9300 cc. per minute—almost twice normal). The arterial blood oxygen saturation was normal, which indicates that the patient did not, on rest, develop anoxemia because she

FIGURE 1. Case 1.

This radiogram of the chest shows only slight changes in the bases of the lungs, in spite of severe respiratory difficulty.

compensated for the impaired pulmonary function by increased respiratory activity.

The patient thus presents a clinical picture similar in every respect to the cases previously reported. She started with typical Raynaud's phenomena; 4 years later, she began to show progressive nutritional changes of the skin of the hands and face; and about 2 years later, respiratory symptoms, marked by severe exertional cough, developed. Study of the pulmonary dynamics and, to a lesser extent, of roentgenograms shows evidence of pulmonary fibrosis.

CASE 2.* M. R., a 45-year-old woman, was first admitted to the Beth Israel Hospital in January, 1940. She gave a history of Raynaud's phenomena of 10 years' duration. A left cervical sympathectomy was performed in 1935, and a right cervical sympathectomy in 1936, following which the hands improved a great deal. Following pregnancy 10 and 12 years previously, the patient had had two attacks of arthritis involving the hands, knees and ankle joints. Tonsillectomy and teeth extractions were performed to eliminate foci of infection. Several months before entry, the patient began to experience dyspnea on exertion that progressed and was associated with severe coughing spells. Five days before entry, she complained of substernal oppression and shortness of breath even while at rest. She had been completely digitalized before admission to the hospital.

On examination, she was found to be slightly cyanotic, and markedly dyspneic. The skin was smooth, warm, dry and slightly blotchy over the face and hands, with nutritional changes. The heart was enlarged to percussion, with a diffuse apical impulse and a rate of 100. There were frequent extrasystoles. A soft systolic murmur was

*I am indebted to Dr. Julius Abramson for permission to report this case.

heard all over the precordium. The pulmonic second sound was louder than the aortic. On one occasion, a diastolic murmur was heard at the apex. The peripheral vessels were normal. The blood pressure was 110/80. The lungs showed dullness at both bases, with medium

FIGURE 2. Case 2.

The congestion shown at the bases of the lungs was assumed to be secondary to the marked degree of cardiac enlargement.

crepitant rales. The liver edge could be felt 3 finger-breadths below the costal margin. There was moderate pitting edema of the ankles. The hands showed arthritic deformities, and there was limitation of motion of the elbows, shoulders, knees and back.

Roentgenographic examination showed a large heart and exaggerated markings at the bases of both lungs (Fig. 2). The patient did very poorly during her stay in the hospital. She was discharged with the diagnosis of rheumatic heart disease, mitral stenosis and regurgitation, right-sided and left-sided cardiac failure and Raynaud's disease.

After discharge from the hospital, the patient was confined to bed at home. She was maintained on digitalis, in spite of which she developed generalized edema and fluid in the chest and abdomen, for which she had to be tapped.

In September, because of severe back pain, she was readmitted to the hospital for further study.

Her condition became progressively worse. The back pain became very severe, and on the 15th hospital day, the patient became irrational and had an elevation of temperature; she expired on the 17th hospital day.

Autopsy. The heart was slightly enlarged, weighing 400 gm. The right auricle and appendage were markedly dilated and hypertrophied. There were no valvular anomalies. Injection and dissection of the coronary vascular tree showed a normal number of atherosclerotic plaques. Microscopic examination showed an increase of the fibrous tissue in the endocardium and in the annulus fibrosus of the mitral valve.

The right lung weighed 340 gm., and the left lung 250 gm. Crepitation was diminished throughout. The lower lobes, particularly the left, were compressed by fluid in the pleural and pericardial cavities. The pulmonary veins

and arteries were moderately dilated. Microscopic examination showed fibrous thickening of the pleura and pulmonary tissue, with engorgement and dilatation of the vessels and infiltration with lymphocytes, monocytes and pigment-laden phagocytes. In many areas, these inflammatory cells were gathered into focal collections. The muscular walls of the bronchi and bronchioles were intact but, in many cases, showed fibrosis. The alveolar spaces were relatively normal in appearance but somewhat smaller than usual. The alveolar walls were definitely thickened and prominent, with an increase in fibrous tissue up to ten to fifteen times normal (Fig. 3). The alveolar spaces showed no evidence of inflammatory reaction. This thickening of the alveolar walls had resulted in partial obliteration of the alveolar spaces, so that many areas appeared to be atelectatic. In some places, thick buds of cells, with indefinite outlines and fibrous stroma, projected from the alveoli into the spaces. Scattered through this dense fibrous reaction were a large number of dense focal collections of these cells. There was no evidence

FIGURE 3. Case 2.

This photograph of a section of the lung shows great thickening of the alveolar walls, owing to fibrotic changes.

of an acute inflammatory process, neoplasm, abscess or infarct. The capillaries were dilated and congested, and in many areas were definitely thicker than normal, suggesting a primary vascular basis for the fibrous thickening of the alveolar walls. The most prominent features, in the lungs, therefore, were the diffuse pulmonary fibrosis, the suggestive arteriolar thickening, with heaped-up nuclei in some areas, and a slight degree of emphysema, with almost normal appearing alveolar walls.

The liver was somewhat enlarged, weighing 1500 gm., and firmer in consistence than normal. There appeared to be a slight increase of fibrous tissue.

The muscles and subcutaneous tissues showed some focal collections of inflammatory cells suggesting chronic myositis.

The significant pathological diagnoses were: enlarged heart; congestive heart failure; and diffuse pulmonary fibrosis.

SUMMARY

Two additional cases of pulmonary fibrosis associated with Raynaud's disease are reported. One case, under observation, showed pulmonary fibrosis by roentgenograms and studies of the pulmonary dynamics. The other, at post-mortem examination, showed extensive pulmonary fibrosis, with changes in the small vessels of the lungs that

were consistent with the vascular changes found in the small digital arteries in advanced cases of Raynaud's disease.

TUBERCULOSIS OF THE FOOT AND ANKLE IN ADULTS AND CHILDREN*

JOSEPH D. WASSERSUG, M.D.†

MIDDLEBORO, MASSACHUSETTS

IN any analytical discussion of tuberculosis of the ankle or foot, a sharp distinction must be made between disease involving the ankle (tibioastragaloid) joint and tuberculosis of the tarsal and metatarsal bones. Disease of the soft tissues and tendons must be differentiated from disease in bones and joints. Furthermore, since treatment and prognosis differ in adults and children, cases in children should be analyzed separately from those in adults, and since tuberculosis may resemble other diseases clinically and roentgenologically, cases that are pathologically proved must not be confused with unconfirmed cases. Finally, if treatment is to be evaluated, cases must be adequately followed.

A review of the literature reveals that oftener than not "ankle" is used as a generic term that includes "foot." Only recently has the need for pathological investigation and proof of tuberculous etiology been stressed.¹⁻³ Cases of disease in adults and children have been mixed together. Differentiation of cases in adults and children has been made by Delahaye,⁴ Miltner and Fang³ and Mitchell.⁵ Adults alone are considered by Dubau and Bolot,² Gaenslen and Schneider⁶ and Rogers,⁷ and children alone are discussed by Sever,⁸ Papin,⁹ Pouzet¹⁰ and Fraser.¹¹ No distinctions, however, are made by Schiller and Altschul,¹² Rollier,¹³ Petrov,¹⁴ Piquet¹⁵ and LoGrasso.¹⁶

This paper represents a study of 46 cases of ankle (tibioastragaloid) tuberculosis and 42 cases of tuberculosis of the tarsus and the metatarsal bones. Cases involving only soft tissues, tendons or the phalanges have been excluded. The patients were admitted to the Lakeville State Sanatorium between the years 1926 and 1940. Since 1134 patients with bone and joint tuberculosis were admitted in this period, this represents an

incidence of approximately 4 per cent for each form.

TUBERCULOSIS OF ANKLE

Of the 46 cases studied, 24 were in males, and 22 in females. Twenty-four cases were in the right ankle, 21 in the left, and 1 in both. The age at onset of symptoms varied from one to sixty-five years, with an average of twenty-two years. On admission, 20 patients were between the ages of one and fifteen, 22 between sixteen and forty-five and 4 between forty-six and sixty-five, the average age being twenty-five years. In 15 cases, a history of trauma was obtained. The family history was positive for tuberculosis in 15 cases. In 39 cases (85 per cent), other demonstrable tuberculous foci were present.

Through the aid of the Social Service Department, 36 cases were followed from two months to fourteen years, an average of six years, after discharge from the sanatorium. Of the 10 patients not followed, 8 died while in the sanatorium and only 2 could not be traced. Excluding these 2 cases, 18 cases were proved pathologically, and in 16 the diagnosis was made only on clinical and roentgenologic evidence. Among the 16 cases, there were 7 deaths—all due to pulmonary, meningeal or urogenital tuberculosis.

Proved cases in adults. In this discussion, an adult is arbitrarily defined as a person sixteen years or older. Of the 28 proved and followed cases, 16 patients were in this group. Fifteen of these had additional tuberculous lesions: other bone and joint lesions were present on admission in 11 cases, and 10 patients had evidence of pulmonary tuberculosis. Multiple lesions were present in 6 cases. Seven of the 16 adults with proved ankle tuberculosis died, 3 while in the sanatorium and 4 within five years after discharge. In but 2 cases, pulmonary tuberculosis or tuberculo-

*From the Massachusetts Department of Public Health.

†Formerly, assistant physician, Lakeville State Sanatorium, Middleboro, Massachusetts.

meningitis was the cause of death. Conservative treatment—that is, sanatorium regime, plaster immobilization, aspiration or incision and drainage of abscesses as indicated—was given to 6 patients, some of whom were seriously ill on admission. Four of these patients died, but good results were obtained in the remaining 2 cases. In 3 cases, an arthrodesis was performed, with poor results in every case. One case required amputation four months after arthrodesis. Amputation was performed two to ten months after admission in 5 cases, with good results in 5 and death in 3.

Unproved cases in adults. Of the 8 cases lacking pathological confirmation, 6 died of tuberculosis, 2 while in the sanatorium and the others within five years after discharge. Five cases were treated conservatively, and in only 1, followed for eleven months, were the results satisfactory. One arthrodesis, 1 amputation and 1 osteotomy were done, and all 3 patients operated on died.

Proved cases in children. Any person fifteen years or younger is defined as a child for the sake of discussion. Twelve cases of proved and followed ankle tuberculosis fell in this group. Two of these patients were hospitalized primarily for other tuberculous lesions, of which they subsequently died. The third death in this group of cases was due to tuberculous meningitis. Of the remaining 9 living patients, 4 were given conservative treatment, with good end results, a satisfactory erosion or curettage was done in 3 cases, and in 2 cases, erosion or curettage required subsequent amputation. The last 2 patients have artificial limbs and get along well.

Unproved cases in children. There were 5 cases in this group, with only 1 death, due to tuberculous meningitis. Five patients were treated conservatively, and good results were obtained in every case. Two cases, treated by erosion, were followed for more than two years, and good results were obtained.

TUBERCULOSIS OF FOOT

Of the 42 cases studied, 23 were in males and 19 in females. Twenty-eight cases were in the right foot, 13 in the left, and 1 in both. The disease may strike any bone or joint in the foot, and in 5 cases only the metatarsals were involved. In 27 cases, more than one bone in the tarsus was affected. A history of trauma was obtained in 17 cases, and in 11 cases a positive family history of tuberculosis was found. Other tuberculous foci were present in 20 cases (48 per cent). The age at onset of symptoms varied from ten months to seventy years, with an average of nineteen and a half years. The average age on admission was twenty-four years.

Thirty-seven cases were followed from five months to fourteen and a half years, an average of seven years after discharge from the sanatorium. Three cases could not be followed. Two patients died while in the sanatorium.

Proved cases in adults. Seventeen patients were in this group. Among these, there were 3 deaths: 1 was due to amyloid disease, 1 to a tuberculous spine and tuberculous nephritis, and 1 to postoperative complications in a patient seventy-one years old. Seven patients were treated by amputation, two weeks to two and a half years after admission, and in an additional case an amputation was performed a year after discharge. Of the amputated cases, 2 patients died, and in the remaining 6 cases the stump is well healed and the end result is satisfactory. An amputation was done in 4 cases that had previously received less radical surgical treatment. Conservative treatment only was carried out in 5 cases, and there were good results in 2, poor results in 2, and death (from tuberculous spine and tuberculous nephritis) in 1. Curettage, not followed by any more radical procedure, was successfully performed in 3 cases. A satisfactory arthrodesis, no graft being used, was performed in 1 case.

Unproved cases in adults. Four cases were found in this group and no deaths. In each case, several tarsal bones were involved: astragalus twice, calcaneus once, navicular twice, cuneiforms three times, and cuboid once. Three cases were treated conservatively, with good results in 2. A satisfactory arthrodesis was done in 1 case a month after admission.

Proved cases in children. There were 8 cases and no deaths in this group. In 6 cases, the end results were good, and in the remaining 2, the end results were fair. In 3 cases, treatment consisted largely of plaster immobilization. In 4 cases, curettage was done, but in 3 of these, the disease was apparently localized to a single bone. An arthrodesis was done in only 1 case.

Unproved cases in children. There were 10 patients in this group, all of whom were adequately followed. One of these children had curettage nine months before admission, and an amputation three months before admission. In another case, a biopsy was done. The remaining 8 patients were treated conservatively, with satisfactory end results in every case. There were no deaths in any of these 10 cases.

DISCUSSION

Tuberculosis of the ankle joint in an adult, whether it is proved pathologically or diagnosed on the basis of clinical and roentgenologic evi-

dence, is a fairly serious condition and is associated with a mortality of over 50 per cent. Of the 24 adult patients in this study, 13 died, 11 of some other tuberculous focus, such as a pulmonary one. The results of prolonged conservative treatment and immobilization are poor, and the end results of arthrodesis are equally bad. Midcalf amputation after a short period of hospitalization offers the best hope for a permanent and rapid "cure." Besides, more attention must be given to extraosseous foci, such as the lungs, and the patients should be watched carefully for the development of activity in what may appear to be arrested lesions.

In children, the prognosis of ankle-joint tuberculosis is better. The children in this study were followed for an average period of five years and eight months, as compared with an average follow-up of five years and ten months for the adults with ankle-joint disease. Of a total of 20 cases in children (12 proved, 8 unproved), there were only 4 deaths. Three patients died of tuberculous meningitis, but these 3 were treated by plaster immobilization and no operation was performed that might account for the metastatic spread of the disease. The fourth death was in a patient who had tuberculosis of the spine, wrist and lymph nodes, in addition to the ankle, and an amputation was performed as a possible lifesaving measure. In children, conservative treatment may be carried out safely for longer periods than in adults, with expectations of satisfactory results. An arthrodesis or erosion can safely be done sometimes in other cases, and in a few, amputation offers the only hope of a good end result.

Tuberculosis of the tarsal and metatarsal bones must be considered a different disease from ankle tuberculosis. The mortality of foot tuberculosis in adults was 14 per cent, as compared with 54 per cent for ankle tuberculosis in adults. Ankle-joint tuberculosis in children had a mortality of 25 per cent, as compared with no deaths for tuberculosis of the foot in children. It is apparent that tuberculosis of the foot is a relatively benign disease, as compared with tuberculosis of the ankle.

Adults with tuberculosis of the foot were treated sooner or later by amputation in 8 out of 21 cases. Fifty per cent of the patients with amputation had had an adequate preliminary trial of sanatorium treatment and more conservative surgery. In 5 additional cases, conservative surgical measures gave satisfactory end results. There were only 4 good end results, however, in 8 patients treated only by bed rest and immobilization. Thus, a short trial of conservative treatment should be given to an adult with tuberculosis of the foot. If this fails, surgery less radical than amputation

offers about a 50 per cent chance of success. Amputation, however, should not be withheld until it is demanded as a last resort.

In 18 cases of tuberculosis of the foot in childhood, there were no deaths. Even in cases in which the foot appears angry, swollen and ridged with sinuses, prolonged conservative treatment must first be given a fair trial. Prolonged immobilization and bed rest (as in a sanatorium) offer the best chance for permanent cure. In 11 of 18 cases, conservative treatment gave good end results. Curettage and arthrodesis are usually unnecessary, but if the disease is apparently localized to a single bone, such as a metatarsal, curettage may be successfully performed.

SUMMARY

Tuberculosis of the ankle joint is a serious complication of pulmonary or other tuberculous lesions and was associated with an eventual mortality, from some form of tuberculosis, of 54 per cent in adults and 20 per cent in children in a series followed for an average period of six years after discharge from a sanatorium.

In the treatment of ankle-joint tuberculosis in adults, amputation should not be unduly postponed; in children, about 50 per cent good end results were obtained with sanatorium treatment and immobilization. In a few others, arthrodesis was successfully performed, but some patients required amputation.

Tarsal and metatarsal tuberculosis is a comparatively benign disease, in contrast to ankle-joint tuberculosis. In adults, it was associated with an eventual mortality of only 14 per cent from some form of tuberculosis and no mortality in children after an average period of seven years' observation.

In adults, about two fifths of the cases of foot tuberculosis required amputation, but a longer trial of conservative treatment can be more safely undertaken than in ankle disease. Conservative treatment in children yielded good results in about 60 per cent of the cases, and other simple surgical procedures, such as curettage, were satisfactory. Arthrodesis or amputation was only rarely necessary.

ed with an unaltered spinal-fluid pressure, the change is probably correctly ascribed to a diminished cerebral metabolism rather than to a variation in cerebral blood flow.² Practically conclusive evidence that this interpretation is correct is obtained by the blood-flow method of Gibbs (Loman and Myerson⁶).

Changes in Caliber of Retinal Vessels

The retinal vessels are outgrowths of the cerebral vessels and are enclosed in a container analo-

of alcohol in physiologic saline solution intravenously, so that they received from 50 to 85 cc. of absolute alcohol. The alcohol was administered slowly for ten to fifteen minutes. All the subjects manifested various degrees of intoxication within a short time after the administration of the drug: drowsiness, silly laughter, talkativeness, euphoria and muscular inco-ordination. Blood was collected from the brachial artery and from the internal jugular vein before the administration of the alcohol and at the height of the alco-

gous to the intracranial cavity. Changes in the diameter of the retinal vessels may indicate similar changes in the caliber of the pial vessels but not necessarily of the intracerebral vessels.

Changes in Velocity of Blood Flow

Alterations in velocity do not necessarily indicate actual changes in blood-volume flow. Since absolutely definite conclusions regarding changes in cerebral blood flow cannot be made in the absence of direct visualization of the cerebrovascular bed, conclusions regarding alterations in flow should be open to some doubt unless data obtained from the various methods coincide.

Because one of the effects of alcohol is flushing, its possible clinical usefulness as a cerebral vasodilator became apparent. Thomas⁷ observed in cats that pial arteries increase in diameter following both the intravenous administration of alcohol and the direct application of the chemical to these vessels. Direct blood-flow measurements showed similar changes. Such effects, however, were noted to be transient, lasting about fifteen minutes. Goldfarb, Bowman and Wortis⁸ found a diminished arteriojugular difference in oxygen in patients admitted to the hospital in a state of alcoholic intoxication. These authors explained the decreased uptake in oxygen on the basis of a decrease in cerebral metabolism rather than on a basis of an alteration in cerebral blood flow.

METHOD USED

In the present experiments, 10 subjects with dementia praecox in good physical health were studied. They were given a 25 per cent solution

holic reaction—that is, between fifteen and thirty minutes after the completion of the injection. Oxygen determinations by the Van Slyke method and sugar determination by the Folin-Wu method on all samples of blood were carried out. In 4 cases, the spinal-fluid pressure was followed during and after the administration of the alcohol.

RESULTS

Oxygen uptake. In only 2 (Cases 1 and 5) of the 10 cases was there a significant decrease in oxygen uptake by the brain following the administration of the alcohol (Table 1); one of these subjects was moderately drowsy, and the other was narcotized to the point of sleep. The other 8 exhibited slight to moderate drowsiness.

Sugar content. The uptake of this substance was not significantly altered during the period of alcoholic intoxication.

Cerebrospinal-fluid pressure. In none of the 4 cases in which this test was performed was there any significant change in pressure.

DISCUSSION

The dose of alcohol used in the present experiments may be considered adequate to test the vasodilating action of the drug. Larger amounts would probably be too depressant to the brain to offset any possible cerebral vasodilatation. It is likely that any diminution of oxygen uptake by the brain following the administration of alcohol is related to a diminished cerebral metabolism rather than to cerebral vasodilatation. In the 2 cases in

which a diminished oxygen uptake occurred, the drowsiness was moderate to marked. The fact that the cerebrospinal-fluid pressure was unaltered during the administration of the alcohol also indicates the inefficacy of alcohol as a cerebral vasodilator. Although the lack of a significant change in glucose uptake by the brain during the alcohol intoxication suggests a change neither in cerebral metabolism nor in cerebral blood flow, it is probable that a change in uptake of this metabolite is an unreliable index of alteration in cerebral blood flow.

Since alcohol acts as a cerebral depressant, it appears not to have any especial advantage over other vasodilators. Several other drugs not having a depressing effect on the brain are known to have a cerebral vasodilating action. Such drugs include carbon dioxide, histamine, the nitrites, acetylcholine and niacin. They all, however, have a transient vasodilating action, and in effective dosage some of them are apt to have undesirable side effects.

It is suggested that effective and prolonged cerebral vasodilatation, with the elimination of undesirable side effects, may be accomplished by slow continuous intravenous infusion. For this purpose, niacin and histamine are probably more desirable than the nitrites and acetylcholine. A mixture of 10 per cent carbon dioxide and 90 per cent oxygen also merits more frequent trial, since carbon dioxide has a specific cerebral vasodilating action (Lennox and Gibbs⁹).

SUMMARY AND CONCLUSIONS

Alcohol was administered by intravenous route to 10 subjects in doses sufficient to produce definite

signs of intoxication. Oxygen and glucose uptakes between the arterial and internal jugular venous blood were compared before and at the height of the intoxication. The cerebrospinal fluid pressure was measured in 4 subjects.

In only 2 cases was there a noteworthy decrease in oxygen uptake by the brain. This change is interpreted as a decrease in cerebral metabolism, rather than as an increase in cerebral blood flow. The uptake of glucose by the brain was not significantly altered, nor was there a noteworthy change in the cerebrospinal fluid pressure.

These data indicate that alcohol is not an efficacious cerebral vasodilator. It is suggested that other drugs, particularly niacin (nicotinic acid) and histamine, may be of value as cerebral vasodilators if given by slow intravenous administration in dilute concentrations. A mixture of 10 per cent carbon dioxide and 90 per cent oxygen is also worthy of more frequent trial in cerebral conditions in which an increased blood flow seems desirable.

MEDICAL PROGRESS

THE TREATMENT OF RHEUMATOID ARTHRITIS*

CHARLES L. SHORT, M.D.,† AND WALTER BAUER, M.D.‡

BOSTON

THE cause of rheumatoid arthritis remains unknown. Although many theories (infectious, metabolic, endocrine, circulatory and neurogenic) have been proposed, no one of them has been generally accepted. This disease presents a variety of clinical forms and pursues no single pattern of development. It must be regarded as a distinct disease entity that can readily be recognized. Space does not permit more than a listing of the outstanding features that distinguish rheumatoid arthritis from other forms of joint disease. It is essential to realize that one is dealing with a generalized disease with well-marked constitutional manifestations that are not merely secondary to the articular lesions. Females are more commonly affected than males, except in cases in which the spine is involved. The onset is not limited to any age group and may occur from infancy to senility. Constitutional symptoms often precede the appearance of objective joint signs, and it is thus possible to surmise the diagnosis in what may be termed a prodromal stage. The type of onset ranges from the insidious to the explosive, with endless variations between. In many cases, the initial complaints are fatigue, exhaustion, lassitude, loss of weight and symptoms referable to the nervous system and the vasomotor apparatus. Both large and small joints are affected, at first perhaps in a migratory fashion but later with unrelenting persistence. Examination of the joints reveals no early findings that are specifically different from those of other forms of arthritis. The signs of inflammation, usually mild and often accompanied by effusion, almost always precede the development of limitation of motion and deformity. More important is the symmetrical, polyarticular distribution of the arthritis, although involvement of one or a few joints is not uncommon in early stages. Muscular weakness and atrophy are prominent, and inflammation of extra-articular fibrous tissue

is almost invariably present, subcutaneous nodules forming a characteristic part of the clinical picture in about 20 per cent of the cases. Involvement of other organs of the body is evidenced in certain cases by cold, clammy hands and feet, atrophy and pigmentation of the skin, lymphadenopathy and splenomegaly, pericarditis and pleuritis, and ocular changes including uveitis and scleritis. The course of the disease is all too often one of steady or intermittent progression, although complete or nearly complete remissions are not unusual at first, and certain patients recover without significant residual disability.

Laboratory studies, although not of diagnostic help, may aid in the determination of the severity of the disease. The sedimentation rate of the red cells and the Schilling or filament-nonfilament counts are useful in following the course of the disease, but only occasionally in differential diagnosis. In approximately 50 per cent of the cases, the serums of patients with rheumatoid arthritis agglutinate strains of hemolytic streptococci of Lancefield Group A in a characteristic manner. In such cases, a positive test is of value in distinguishing rheumatoid arthritis from other forms of arthritis in which positive agglutinations are encountered only rarely. Unfortunately, the test is rarely positive in patients having the disease less than one year. The antistreptolysin and antifibrinolytic titers in rheumatoid-arthritis serums are not characteristic, whereas rheumatic-fever serums usually show elevated values. Biopsy of subcutaneous nodules is frequently of aid in differentiating the former disease from the latter. Examination of synovial fluid is helpful in ruling out traumatic arthritis, degenerative joint disease and the specific infectious arthritides. A hypochromic anemia is often found in severe cases. The white-cell count varies considerably. In most cases, it is within normal limits or only slightly elevated. In the acute and active stages, counts of 12,000 to 20,000 may be observed, whereas in long-standing, chronic cases a definite leukopenia may develop.

Roentgenograms in joint disease must always be interpreted in the light of the duration, severity and articular distribution. With the aid of such facts, accurate roentgenologic diagnosis of rheumatoid arthritis is usually possible. The characteristic features include soft-tissue swelling, effusion,

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress: Annual, Vol. III, 1942* (Springfield, Illinois: Charles C Thomas Company, 1942. \$5.00).

systemic decalcification of bone, loss of bony substance in "punched-out" areas, narrowing or even obliteration of the joint space, marginal erosion and, finally, subluxation and gross bony destruction. No single feature mentioned constitutes a diagnostic criterion, and it has been truly said that the picture differs from that of specific infectious arthritis largely in speed of progression.

Because of limitation of space, points helpful in differential diagnosis are not considered at length. Those interested in this aspect of the subject are referred to a previous report.¹ However, it should be emphasized that although rheumatic fever in its classic form is readily recognized, the acute type of rheumatoid arthritis, as well as rheumatic fever tending toward long-continued joint involvement, may render accurate diagnosis extremely difficult. At the present state of knowledge, it must be assumed that the development of endocarditis signifies the coincidental presence of rheumatic fever. A migratory arthritis, tending to complete remission and restitution of joint function, is, of course, strongly in favor of rheumatic fever. Erythematous skin lesions, electrocardiographic changes and rapid response to salicylization are also helpful in the decision for this diagnosis. The subcutaneous nodules in rheumatic fever tend to appear in crops, are transitory, and usually disappear before reaching the size of those found in rheumatoid arthritis; as previously stated, they can be differentiated at biopsy, but only by a pathologist experienced in this field.² In many cases, final decision between the two diseases must be left to the passage of time. Fortunately, nothing is lost by reservation of judgment, since the treatment is essentially the same for both diseases in this stage. The physician should not be afraid to admit the necessity for the passage of time to give the answer, since the patient is only too glad to learn that there is a reasonable doubt that he is suffering from a potentially crippling disease. It should be emphasized that the diagnosis of rheumatoid arthritis should never be made without due consideration and that the disease deserves the same respect and care accorded pulmonary tuberculosis and cancer.

TREATMENT

Because the cause of rheumatoid arthritis is unknown, there is no specific therapy directed toward an etiologic agent. The evidence at hand points to an unrecognized infectious origin. Measures to increase the patient's resistance and place him in the best general health, in addition to proper handling of the inflamed articulations to promote healing and preserve function, are therefore in order. Once the diagnosis has been made, the patient should know what is ahead of him

and should be informed that there is no easy and rapid road toward arrest of the disease. He should also be made acquainted with the natural course of rheumatoid arthritis, so that he will not relax his precautions as a result of a remission or become overly depressed from a relapse. An optimistic, courageous, resourceful attitude is a requisite for the physician who would successfully treat this disease and not see some of his patients wander off to patent remedies and quacks. He must even at times compromise with his intellectual honesty and employ methods of doubtful value, to hold the patient to the pursuit of a few simple measures of proved worth. Thus, the use of vaccines or other parenteral medication of unproved value, combined with generous measures of suggestion, may tide the patient over a discouraging period when the disease seems to be at a standstill or progressing in spite of all efforts.

Treatment varies, of course, according to the stage in which the patient is seen. In the initial, acute attack, there is a very good chance of remission or even arrest of the disease. Continued rest and care after symptoms have apparently subsided are well worth the time and money expended. In patients in whom the disease is well established but relatively quiescent, the physician can temporize and attempt to adapt the scheme of treatment to the patient's occupation and habits, being careful, however, to resume restrictions at the first definite sign of an exacerbation. Instruction should always be definite and detailed, preferably written out. The possibility of a remission when things look darkest should never be lost sight of. The startling freedom from symptoms gained from intercurrent hepatic jaundice or pregnancy points out that the process is not irreversible and that the long-awaited specific method of treatment may yet come to light. Most students of the disease are of the opinion that the treatment of rheumatoid arthritis can be divided as follows: measures of proved value; and measures frequently employed but of questionable value.

Measures of Proved Value

It is agreed that general measures—including rest of the whole patient and of the joints, along with an attempt to preserve, so far as possible, the function of the articulations and muscles—form the backbone of the treatment of rheumatoid arthritis. Realizing the difficulty of evaluating therapeutic claims, one should never be too dogmatic in stressing the value of any single measure. Hospitalization is always of benefit when the patient is first seen, not only for the more adequate care of severe cases but also for diagnostic studies and observation if needed, to teach the patient principles and methods that can later be pur-

sued at home and to provide orthopedic apparatus. How long such treatment should be continued will depend on individual factors such as the course and severity of the disease, the patient's financial resources and the suitability of conditions for care at home.

Rest. Complete rest in bed is essential in certain forms of the disease. The first is made up of acute febrile cases with severely inflamed joints and often resembling a specific infectious arthritis or rheumatic fever. Other forms include rapidly progressive cases, although the patient may be afebrile and the joints not acutely inflamed, patients with marked constitutional manifestations and, finally, those whose weight-bearing joints are so inflamed or deformed as to make walking unwise. The duration of bed rest, of course, depends on the patient's response. In general, this situation is very much like that in pulmonary tuberculosis in which, to ensure against reactivation of the disease, rest must be prolonged even after the patient has started to improve. Similarly, the process of getting up must be gradual and guarded. Sitting on the edge of the bed or in a chair for ten to fifteen minutes is all that should be allowed at first, with increases slowly granted and gauged according to the patient's response. The physician must outline carefully the extent and duration of bed rest as soon as he has been able to estimate the necessary program, with the provision that unforeseen changes may force an alteration in the plan.

The patients with milder cases who do not need bed rest when first seen, and those who have improved beyond that stage should continue to obtain more rest for an indefinite time. This may vary from ten to twelve hours in bed each night, in addition to an afternoon nap, to bed rest from eighteen to twenty hours out of the twenty-four. In such patients, the symptom of fatigue is as important a guide as the state of the joints. In other words, fatigue is a condition to be avoided at all cost—a principle to be learned and followed by the patient himself. If the patient is confined to bed for a long period at home, a hospital bed with an adjustable spring and mattress is well worth the rental or purchase price to both patient and attendant. If the lower extremities are involved, a cradle or footboard is often necessary. The need for nursing care, of course, varies with the individual case. A practical or household nurse usually suffices if carefully directed by the doctor. If nursing care is unavailable or unnecessary, a responsible member of the household should be chosen to act for the physician to see that the course of the treatment is faithfully carried out. Finally, rest can be aided

materially by the judicious use of analgesics and hypnotics. Their use is described below.

Treatment of joints. Rest of the involved joints promotes healing and is often essential to the comfort of the patient. Weight bearing should not be allowed on acutely inflamed joints or those with heat or atrophied muscles, or both, or fixed in poor weight-bearing line. Once weight bearing is allowed, protection by means of bandages, splints or crutches is usually necessary. The production of subcutaneous nodules in points exposed to irritation furnishes an indication that rheumatoid tissue is affected adversely by trauma. Rest of joints also affords relief from muscle spasm and tension and allows for a decrease in swelling. The use of splints or casts further allows the joint inflammation to subside, keeps the joint in an optimal position for function and protects against the deforming influences of muscle spasm and gravity.

Prevention and correction of deformities are vital in the treatment of this disease. In many patients with arthritis, severe deformities and contractures occur in joints that have received inadequate splinting. The physician must be alert to this possibility and forestall it by careful splinting of the affected joints in the position of optimal function. Molded plaster splints or bivalved plaster casts are the most comfortable and efficient devices for the feet and knees. The plaster should be shaped so that the foot is supported at a right angle to the leg, and the arch carefully molded, with additional support just behind the metatarsal heads so that the toes are kept straight. The plaster should extend beyond the toes, and a crossbar of wood should be incorporated at the heel to prevent outward rotation deformity of the hip. It should extend upward to the gluteal fold.

Although continuous use of these protective appliances is necessary at first, they may later be used only at night or for certain periods during the day. When casts are employed, they should be bivalved after the first few days so that the joints may be given physical therapy (exercises, massage and so forth). From the very beginning, a determined effort must be made by physician and patient to preserve articular function. Even if the joints are acutely inflamed, a gentle, guided and supported movement or two is possible each day and is immeasurably helpful in the prevention of adhesions and ankylosis. Later on, systematic active exercises such as are used in anterior poliomyelitis should be performed several times daily, limited only by fatigue and pain, not during but persisting after the exercises. Regular exercises probably aid in the absorption of exudates and encourage the will and discipline of the patient. Along with such exercises of the joints, the patient should be

taught to assume a supine position, with the bed flat, for increasing periods up to several hours a day. At this time, breathing and postural exercises can be done. Even if experienced in the treatment of rheumatoid arthritis, the physician will do well to seek the advice and aid of the orthopedist both at the beginning and at regular intervals in the course of the treatment of any patient whose joints are severely involved.

Physical therapy cannot be dispensed with in the treatment of rheumatoid arthritis. The knowledge that heat, exercise and massage are beneficial in the treatment of this disease probably antedates all recorded medical teaching. Unfortunately, there is still no adequate knowledge of the mechanism by which these measures give relief, and one must prescribe physical therapy largely according to its effect. The joints and periarticular structures of most patients with rheumatoid arthritis are less painful and move more freely after the application of heat. A few exceptions are found in patients with acute, severely inflamed joints and in the not uncommonly encountered persons whose joints are more painful when heat is applied. For the first group, simple fixation should be used until the inflammation subsides; for the second, the patient's word should be immediately accepted and heat withheld or even a trial made with cold applications. There is no scientific and little clinical evidence that any form of heat is superior. In the hospital, local diathermy or carefully applied hot packs may be serviceable; in the home, an inexpensive electric baker or an electric pad can be employed. The duration of the application of heat should not cause tiring or discomfort. Several brief applications a day are better than one more prolonged. In general, a visible reaction should be effected, with reddening and sweating of the overlying skin. If excessive fluid or salts are lost in the sweat, with a weakening effect, water and sodium chloride must be supplied.

When multiple joints are involved, immersion of the patient in a hot bath or under a hot shower often relieves symptoms. This form of treatment is not indicated in debilitated patients or in those with too active an arthritis to permit movement to a tub or shower. The length of the patient's stay in the water should be gradually increased up to a maximum of half an hour. The bath may be given every day if well tolerated, the most effective time being the morning. A safe bath temperature to begin with is 100°F., but this can often be increased as time goes on. If the patient complains of perspiration accompanied by weakness during this course of treatment, extra sodium chloride must be supplied. Immersion of the ex-

trémities in contrast baths (hot water followed by cold) is of value in certain cases; these are usually cases with less advanced changes, but again the decision must be made on the response of the patient. If increased pain is caused by contrast baths, heat alone should be applied. The best schedule to follow is: immersion in hot water for six minutes, immersion in cold water for four minutes, immersion in hot water for six minutes and so on, for a total of seven times, four hot and three cold.

Pools similar to those employed in the aftercare of poliomyelitis to allow exercise of the legs without weight bearing are of value if available. Massage given in the pool should be gentle and applied to muscles rather than to joints.

Fever therapy is often beneficial for patients in good general condition in whom the disease is stationary or gradually progressive. No dramatic, curative results can be expected, but the patient's symptoms may be temporarily improved and his determination thus strengthened. In a few cases, the gain following fever therapy may be held and even increased in the course of general treatment. The various methods of providing fever can be used according to their availability.

No specific effect of sunlight on the course of rheumatoid arthritis has been demonstrated, but its use in control dosage may aid the patient's appetite and sense of well-being. If the patient can be exposed to the sun fairly regularly, vitamin D preparations can be dispensed with. Excessive exposure to sunlight should be avoided.

Surgery and manipulation of the joints are often indicated in the treatment of rheumatoid arthritis. With proper selection of cases and procedure, and with close attention to operative detail and follow-up care, marked improvement in joint function may be expected from certain orthopedic operations. However, there are many pitfalls to be avoided, and it is only after the most careful study of the individual case and under skilled supervision that operative intervention is to be undertaken. It is impossible to give more than a list of the types of procedures available, with a few of their indications.

Whenever possible, deformities should be corrected by the simplest method that will suffice. Daily gentle stretching of quiescent but stiff joints is the safest procedure of mobilization. In many cases, one may safely straighten a flexed knee by applying a cast in maximal correction, bivalving the cast and, after a few days to a week of physical therapy, applying another cast. With each change of plaster, it is usually possible to gain further correction until the knee deformity is completely overcome. Although this method is slow,

it is very comfortable and avoids many dangers of the more forceful methods. Acute deformed joints may often be put in correct position by gentle manipulation under light general anesthesia. The new position should be maintained by proper splinting or a carefully applied cast that is not disturbed until the reaction from the manipulation has subsided. Wedging casts are often employed for the correction of knee-flexion deformity but are contraindicated if there is evidence of an acutely inflamed synovial lining or posterior subluxation of the tibia on the femur. Extreme care is necessary if pressure sores are to be avoided. Adhesive or skeletal traction, often combined with posterior capsuloplasty, may be resorted to in the severer and more intractable knee-flexion deformities. Synovectomy is definitely contraindicated in the acute phase of rheumatoid arthritis, but certain knees, which under prolonged conservative care have failed to become quiescent, are much improved by a subtotal removal of the synovial membrane.

A joint that is so destroyed by the pathologic process that all useful motion has been lost and yet remains painful presents a problem in selection of operative procedure. The choice rests between arthrodesis and arthroplasty. The former has the advantage of practically assuring a pain-free joint, and the operation may be performed while the disease is still active; the wrists, shoulders, hips, knees and ankles are most frequently selected for arthrodesis. Arthroplasty—that is, the restoration of motion in an ankylosed joint by operative means—should be undertaken only after the most careful consideration of many factors. The joint and all other joints must be in a quiescent phase. If there is a recrudescence of the disease, the operation usually fails. Since the postoperative care is prolonged and often painful, the patient should be co-operative and not hypersensitive to pain. The elbow, interphalangeal joints of the fingers, the hip and the knee are the most favorable joints for arthroplasty. Osteotomy may be used occasionally to improve the position of an ankylosed joint.

Diet. The patient with rheumatoid arthritis has long been subject to varying forms of dietary restrictions. Because of the age-old confusion of the disease with gout, he may still be deprived of the vital body-building substances contained in meat. The citrus fruits, which are the best known source of vitamin C, should not be deleted from the dietary of the patient with rheumatoid arthritis because of their supposed "acid-producing qualities." A low-calorie diet with carbohydrates reduced to a minimum should not be prescribed for a patient whose weight and energy are below par. No ex-

perimental evidence adequately supports the majority of the diets that have been used in the past. Carefully controlled clinical studies³ have shown benefit rather than harm from the employment of diets high in proteins and carbohydrates and containing large amounts of citrus fruits. No one food or class of foods needs to be restricted in the diet of a patient with rheumatoid arthritis.

There is no proof that the etiology of this disease lies in a dietary deficiency. Clinical experience has repeatedly shown that therapy based on the supplying of one or more dietary factors in normal or excessive quantities offers no hope of success. Nevertheless, a surprising amount of improvement in energy and nutrition may often be gained from dietary therapy alone. On what must be admitted are for the present largely empirical grounds, we believe that a patient with rheumatoid arthritis should receive a diet that is more than adequate in every respect, with the calories adjusted to the patient's energy requirements and weight. Since weight loss is common, a high-calorie diet is usually required. To aid in combating the diffuse and local bone atrophy that is frequently present, the diet should be abundant in calcium and phosphorus, with sufficient additional vitamin D in concentrated form to ensure complete absorption of these minerals from the gastrointestinal tract. For the treatment or the prophylaxis of the hypochromic anemia that may accompany severe cases, a sufficient supply of iron and meat (especially liver) must be prescribed. Provision should also be made for an ample intake of the other important vitamins. Carbohydrates need be restricted only if the patient is overweight or if such restriction is necessary to provide for an adequate intake of more essential factors. Such a diet supplies a sufficient amount of roughage, which may require curtailment if the patient possesses an overirritable bowel. In summary, the diet of the patient with rheumatoid arthritis should contain as much fresh fruit and fresh vegetables as possible, at least two glasses of fruit juice or tomato juice, seafood, fowl or meat of any kind and two or three glasses of milk. He should be allowed butter, cream, cheese and eggs as desired. The rest of his diet can be adjusted to his own choice, provided he does not gain too much weight.

Vitamins. As stated above, rheumatoid arthritis does not originate from vitamin deficiency and cannot be cured by the administration of normal or excessive amounts of vitamins. The prescription of concentrated vitamins is warranted only on the basis of securing a well-balanced dietary intake containing optimal amounts of the necessary constituents. For this purpose, but with no

thought of a specific effect, we usually advise the patient to partake of vitamin concentrates in addition to a well rounded diet.

Besides containing vitamins A and D, cod liver oil in dosage of 2 or 3 ounces (60 to 90 cc) daily is unsurpassed in its ability to put weight on a patient. If a gain in weight is unnecessary or undesirable, or if the patient is unable to take cod liver oil, vitamins A and D may be supplied in concentrated form. Although the decalcification noted in rheumatoid arthritis has not been shown to be secondary to a primary disturbance in calcium and phosphorus metabolism, it seems reasonable not only to supply adequate amounts of these minerals in the diet but also to ensure their absorption from the gastrointestinal tract. Recently, reports have claimed that marked clinical improvement follows the administration of massive doses of vitamin D (150,000 to 1,000,000 U.S.P. units daily). Carefully controlled studies by others⁴ have shown that such dosage does not alter the course of the disease and, in addition, exposes the patient to the discomfort of nausea and vomiting and other toxic manifestations and the dangers of persistent hypercalcemia. For these reasons, we do not recommend the use of vitamin D preparations in amounts above the usual therapeutic dosage (5000 to 10,000 U.S.P. units daily).

In addition to its role as a part of the normal human dietary, the vitamin B complex may be useful in promoting appetite and normal functioning of the gastrointestinal tract. Occasionally, when prescribed as brewer's yeast or yeast concentrate tablets, this form of medication defeats its own purpose and causes digestive upsets. In such cases, thiamine chloride may be prescribed alone in dosage of 1 to 3 mg daily, or with the addition of riboflavin and niacin (nicotinic acid).

Recent studies have shown that many patients with rheumatoid arthritis have a subnormal level of vitamin C in the blood. Furthermore, such patients have a greater demand for vitamin C and can tolerate a large intake without much loss in the urine. In spite of this interesting therapeutic lead, carefully controlled studies have failed to show improvement in the course of the disease, even though 200 mg or more of vitamin C are administered daily for as long as eight months. For patients who are able to take 8 ounces of orange juice daily, extra amounts of vitamin C in crystalline form appear to be superfluous.

Climate That the symptoms of rheumatoid arthritis may be enhanced by dampness or changes in weather is known to the man in the street as well as to the student of the disease. There is little proof, however, that climatic conditions and dampness bear a direct etiologic relation to the

onset of the disease. Rheumatoid arthritis is said to be rare in the tropics, but further work in geographic pathology is necessary to establish this point. Patients who migrate to a warm, dry climate usually do not improve unless the disease is actively supervised and treated. It is reasonable that a patient with rheumatoid arthritis, if only for his own comfort, should avoid chilling and dampness and should wear warm outer and inner clothing in the winter season of the temperate zone. Whether or not he should move to a warm, dry climate is another question. Such a move should certainly not be made at great financial sacrifice and should not involve giving up the possibility of a gainful occupation. A period of at least six to twelve months must be devoted to the project to make it worth while. A definite arrangement should be made beforehand so that the patient can receive proper treatment and supervision. Most of the advantages from change of climate are probably due to the fact that because the patient has made this radical step, he is willing to go still farther and put himself under sanatorium treatment. A stay in the South may be of great benefit to an occasional patient who will accept regulation and supervision only under the guise of climatotherapy. Although a winter in the South is a pleasant luxury for the patient who can afford it, in most cases the disease must be combated in the patient's own environment.

Foci of infection Irrespective of the claims made by various workers concerning the role of foci of infection in the production of rheumatoid arthritis, most students of the disease agree that it is as great a problem today as before the introduction of the theory of focal infection. A careful and conservative attitude is indicated. The best one can do is to lay down certain principles and indications. If the arthritis follows directly on an infection susceptible to treatment, such as an attack of tonsillitis, focal removal is wise. We have found that such patients bear some liability to exacerbations in the arthritis following subsequent attacks. Focal removal should never be used to the exclusion of valuable general measures or to delay their execution. Expensive combing of the patient for sources of infection is rarely warranted, and consultants' reports must be interpreted and acted on by the doctor in charge of the patient. The evidence is distinctly against the importance of the gall bladder, appendix, bowel (constipation) and male and female genitourinary tracts as foci of infection. Therefore, medical or surgical measures for these regions should be employed only as indicated to improve the general health of a patient without arthritis. The role of dental

infections, especially the pulpless tooth, has probably been exaggerated. Even if infection is demonstrably present, the practitioner may be justified in advising against the extraction of necessary teeth in debilitated patients and thus running the risk of interfering with their nutrition. Advanced cases are rarely benefited by focal removal unless this is essential for their general health. In patients over fifty, the risks of anesthesia and operation must be considered. As is apparent, we have adopted a conservative attitude, which we consider justified at present.

Drug therapy. Like other chronic diseases of unknown origin, rheumatoid arthritis has not suffered from a paucity of remedies of supposed curative value. For our purpose, an exhaustive listing and discussion of drugs of unproved worth is unnecessary and would merely be confusing. We shall, therefore, confine ourselves to drugs of value in the relief of symptoms. The so-called "specific measures" that merit attention either from a certain amount of favorable evidence or from the combined notoriety of enthusiastic clinical reports and extensive advertising will be discussed in a subsequent section.

Relief of pain is of paramount importance in the treatment of rheumatoid arthritis. Pain interferes with rest, sleep, exercise and appetite—all critical factors in recovery. It has been shown that pain decreases peripheral circulation and muscle function, presumably through nervous reflexes. In certain cases, the patient would be reasonably well, so far as articular function or constitutional symptoms are concerned, were it not for the presence of persistent disabling pain. Without denying that measures such as rest, physiotherapy, fixation of joints and even psychotherapy play a major part in lessening pain, in many cases the physician should rightly resort to the use of drugs until the symptoms can be controlled by other methods.

The salicylates rank first for this purpose from the standpoint of both safety and efficacy. Aspirin is usually more effective than sodium salicylate, which, however, is less likely to cause gastric symptoms. The amount used should depend entirely on the patient's response, care being taken, of course, to fall short of toxic manifestations. Many patients need 10 gr. (0.6 gm.) every four hours, and others as much as 15 to 20 gr. (1.0 to 1.3 gm.) every three hours. Since so many patients with rheumatoid arthritis suffer pain and stiffness in the early morning hours and are relatively free later on in the day, the first dose may be given as soon as the patient awakens, followed by another after breakfast. The addition of sodium bicarbonate or the substitution of equal doses of phenacetin often serves to allay gastric disturbances. Phenacetin is also useful in patients who

are not entirely relieved by aspirin. Proprietary preparations, usually with the salicylate radical or aspirin as a basis, have not been found more effective except that they are occasionally better tolerated by the stomach. Although ammonium ortho-iodoxybenzoic acid (Amidoxyl) given intravenously in 1 per cent solution sometimes relieves pain for several days or longer in a stubborn case, this drug must be considered an entirely symptomatic rather than a specific remedy, and care must be taken in its administration to avoid unpleasant reactions. Products containing aminopyrine (Pyramidon) had best be entirely dispensed with if possible on account of the rare but real possibility of a serious or fatal granulocytopenia. The same caution applies to cinchophen and compounds that may cause severe, often fatal, liver damage.

If the salicylates are not entirely effective, codeine in amounts of $\frac{1}{4}$ to 1 gr. (0.017 to 0.067 gm.) may be added to each dose of salicylates. The physician should remember that codeine alone is a much less effective analgesic than in combination with the salicylates. Only occasionally is the use of morphine, pantopon or dilaudid justified. We cannot overemphasize the dangers of addiction in a patient with a chronic disease.

Hypnotics are valuable for patients unable to sleep, unless the insomnia is clearly due to pain. The use of these drugs in rheumatoid arthritis does not differ from that in other conditions, except that special care should be taken to avoid depression the next morning. The combined use of a hypnotic and an analgesic at bedtime is often more effective than either alone. Patients in whom it is suspected that part of the symptoms may be due to emotional causes are benefited by mild continued sedation such as that obtained from phenobarbital, $\frac{1}{4}$ to $\frac{1}{2}$ gr. (0.017 to 0.033 gm.), four times daily.

Novocain block usually gives temporary relief to a painful extremity that fails to respond to other measures. At times, the relief of pain is held, the vicious cycle of pain, muscle spasm and disability apparently being broken by one or two infiltrations with an aqueous solution of 2 per cent novocain above the affected joint. Further trial should be made of this method.

Transfusions. If the anemia present fails to respond to iron in adequate dosage, blood transfusions are needed to bring the hemoglobin and red-cell levels to normal. In addition, transfusions in certain cases apparently may initiate a striking remission. If tried, at least two, of 500 cc. each, should be given.

Psychotherapy. The temporal relation of disturbing environmental factors to the onset and exacerbations of rheumatoid arthritis has long been noticed and recorded in isolated cases.

Recent studies⁵ of an unselected group of patients with rheumatoid arthritis compared with a control group with varicose veins have shown such a relation to exist in a significant number of cases. Without implying that rheumatoid arthritis is of psychogenic origin, we do believe that the physician must recognize the fact that worry, grief and anxiety can be major contributory factors in the progression of this chronic disease. In certain patients, symptoms of undoubtedly functional origin, even classic hysteria, may be superimposed on those due to the arthritis itself. Since pain may be present, apparently out of all proportion to the activity and extent of the disease, the burden of proof should be on the physician to determine that fears and conflicts are responsible for a low threshold of sensitivity. In a few patients, superficial investigation along these lines is revealing and rewarding, the excessive pain being strikingly relieved by the sympathetic listening and encouragement of the physician. In all patients, the initiative, leadership and resourcefulness of the doctor count heavily in whatever success is obtained. A set routine to be carried out according to detailed instructions is valuable from the point of view of suggestion. Equal benefit is obtained by a change in the routine from time to time, both according to the progress of the disease and to maintain the patient's interest and confidence.

Measures Frequently Employed but of Questionable Value

Vaccines. That no theoretical basis exists for the use of vaccine therapy in rheumatoid arthritis rests on two considerations: we are not acquainted with a single disease of known cause in which vaccine treatment is effective; and there can be no specific vaccine for a disease of unknown etiology, and organisms isolated at random from the nasopharynx or stools cannot be deemed specific even with positive skin and complement-fixation reactions.⁶ Since the therapeutic results are negative in carefully controlled series of cases,⁷ one may conclude that there is neither clinical nor theoretical ground for the use of vaccines in rheumatoid arthritis. As mentioned above, there is no objection to their use in patients who are doing badly or standing still, to afford the doctor opportunity to continue with general measures of value and keep the patient under supervision. The same thing applies to the injection of various foreign proteins, including milk and peptone.

The intravenous injection of typhoid vaccine in amounts sufficient to cause a rise in temperature falls under the section on fever therapy.

Sulfur. Recent careful studies⁸ have shown that a primary disturbance in sulfur metabolism is not present in rheumatoid arthritis. Clinical evidence

of benefit from sulfur therapy rests on premature, poorly controlled and overenthusiastic reports.⁹ With the data available at present, sulfur, whether administered by mouth or parenterally, has no place in the treatment of rheumatoid arthritis.

Large doses of vitamin D. As stated above, the administration of excessive doses of vitamin D has no place in the treatment of rheumatoid arthritis. Furthermore, the administration of vitamin D in the amounts advocated by some workers is not without harm to the patient.

Cobra venom. This substance has been successfully used in the treatment of intractable pain due to cancer. Carefully controlled studies in this clinic¹⁰ have shown this form of treatment to be ineffective in relieving the pain of rheumatoid arthritis.

Bee venom. In spite of the advocacy of bee venom by certain workers, the preliminary reports concerning its use have been favorable in only a small percentage of cases. The good results have not as yet been substantiated, and its use is therefore not recommended.

Chaulmoogra oil. There is no indication for the use of chaulmoogra oil in the treatment of rheumatoid arthritis.

Arsenic and iodides. These drugs have long enjoyed an undeserved reputation in the treatment of rheumatoid arthritis, their supposed action being vaguely explained as that of "alteratives."

Endocrine therapy. No endocrine preparation has been shown to exert a specific effect in rheumatoid arthritis. There is no evidence of hypothyroidism in this condition, and treatment with thyroid has been unsuccessful in our hands, even in relieving the vasomotor symptoms by increasing the peripheral circulation.

Although the disease shows a high incidence in women of menopausal age, a direct connection between the menopause and the onset or progress of the disease has not been demonstrated. Replacement therapy with estrogenic material may be used legitimately for relief of distressing menopausal symptoms but not with the hope of altering the arthritis.

Adrenocortical preparations do not help the asthenia so often noted in rheumatoid arthritis, although the pigmentation, low blood pressure and extreme weakness may suggest Addison's disease.

Skeletal decalcification is common in rheumatoid arthritis, but metabolic studies have not shown that this is due to overactivity of the parathyroid glands, and their removal is not indicated.

Gold. Since their introduction by Forestier¹¹ about ten years ago, gold salts have been used extensively in the treatment of rheumatoid arthritis on the Continent and in England. This form of therapy has been slow to gain acceptance in the

United States, largely owing to the dangers of toxicity. Recently, carefully observed series of cases have appeared in the American literature. Writers on the subject have been almost unanimous in stating that although toxic reactions are common and occasionally serious, gold therapy constitutes the most valuable form of treatment known at present for rheumatoid arthritis. Because of the importance of the subject and the limited space available, we shall defer detailed comment on this form of therapy. At present, we are convinced that further experience is necessary before we shall know the therapeutic value of gold in rheumatoid arthritis, to say nothing of how it works to produce its effects. From the figures in the literature and from our own preliminary results,^{12, 13} the case for gold as a specific treatment of rheumatoid arthritis remains unproved. Further work will decide whether this form of therapy merits the acclaim given it by some workers. It is not constantly effective, and it carries a danger of toxicity too great for any but an indispensable drug.

TREATMENT OF RHEUMATOID SPONDYLITIS

Involvement of the spine may precede, accompany or follow rheumatoid arthritis of the peripheral joints. Contrary to the usual sex distribution, the spinal form of the disease is vastly commoner in males. The general treatment outlined for rheumatoid arthritis is equally applicable to this form of spondylitis, which is also called "spondylitis deformans," "spondylitis rhizomelica" and "Strümpell-Marie Arthritis." Removal of the foci of infection is of unproved benefit. If untreated, these patients usually develop severe spinal deformities and, often, hip and knee flexion deformities. As soon as the diagnosis of rheumatoid spondylitis is made, therefore, the physician should devote every effort to keeping the patient's spine in optimal position. The patient should sleep on a firm hair mattress, with fracture boards beneath it, or on a Bradford frame or in a plaster body shell lined with felt. A flexion deformity already present may be corrected slowly by stretching of the dorsal spine over a blanket roll for fifteen-minute periods, three or four times daily. Gentle hyperextension under general anesthesia, repeated at fortnightly intervals if necessary, may be used if other methods fail. As the deformity is reduced, the bed or plaster shell is altered to fit the spinal curves. Deep-breathing exercises should be prescribed and carried out at least three times daily. The abdominal, gluteal and intrascapular muscles should be faithfully exercised. If the hip and knee joints are acutely involved, adhesive traction may be necessary. When the patient is able to be up, the spine should be protected by a carefully fitted Taylor back brace or removable plaster jacket until it has become completely quiescent. The cervical

spine may need traction with a head sling during the very acute stage. Later, a Thomas collar, made from Bristol board, padded with felt or sponge rubber and carefully fitted to the neck, shoulders and mandibles, gives adequate support. If the spine becomes solidly ankylosed, symptoms disappear, and apparatus may be discarded.

Progressive involvement of the hips presents a problem as yet unsolved. During the early stages, every effort should be directed toward the prevention of flexion deformity, so that walking will not be interfered with unduly, but if the progress of the disease cannot be arrested short of ankylosis of the hips, they should be placed in a position of 30° to 60° flexion so that the patient will be able to sit comfortably. The same general plan should be followed for knee involvement. The restoration of joint function by means of arthroplasty of the hips is very difficult of attainment and should be attempted only by a skilled orthopedic surgeon. The employment of a vitalium metal cup over the femoral head, as described recently by Smith-Petersen,¹⁴ gives far better results than the use of fascia lata. Deep x-ray therapy to the spine and sacroiliac joints is occasionally helpful in the relief of symptoms but does not arrest the progress of the disease:

* * *

It is hoped that this brief review will convince many doubting physicians that good therapy is available for the patient with rheumatoid arthritis, and that if it is carried out religiously and with enthusiasm, it will frequently give very gratifying results.

CASE RECORDS OF THE
MASSACHUSETTS GENERAL HOSPITALANTE MORTEM AND POST MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 28381

PRESENTATION OF CASE

A sixty five year old man was admitted to the hospital because of intense abdominal pain.

For more than five years before admission, the patient had suffered with a feeling of fullness and gas after meals. Occasionally, brief attacks of epigastric pain occurred that were not related to food indiscretions and bore no apparent relation to meals. These symptoms were relieved by cream of tartar. The patient also employed cream of tartar as a laxative, however, the constipation was only of a mild type. He occasionally noticed bright red blood on the outside of his stools, particularly after a "drinking" bout.

Six hours prior to admission, while straining at stool, the patient felt "something explode" with in his abdomen. Extreme nonradiating pain developed about the umbilicus. He did not vomit or move his bowels. He had been well the night before and had had a normal bowel movement on the previous day. He then drank a small amount of water, which was immediately vomited. The pain rapidly increased in severity and became widespread, but was severest in the epigastrium and about the umbilicus. The patient did not suffer with chills or fever. He had never suffered a similar previous attack.

The family and past histories were irrelevant except that the appendix had been removed eight years previously at this hospital.

Physical examination revealed a thin, restless man who was obviously extremely ill. He groaned and complained severely of his pain. Examination of the heart and lungs was negative. The abdomen was extremely rigid, but not distended. The abdominal wall was tender even to light palpation, particularly about and to the right of the umbilicus. No peristaltic sounds were audible. Rectal examination revealed a moderately enlarged prostate and a posterior internal hemorrhoid.

The blood pressure was 130 systolic, 80 diastolic. The temperature was 99°F, the pulse 80, and the respirations 26.

Examination of the blood showed a red cell count of 3,880,000 with a hemoglobin of 70 per

cent, and a white cell count of 20,700. The urine had a specific gravity of 1.015 and was acid in reaction, and the sediment contained 10 to 20 hyaline casts, 1 granular cast and 4 or 5 white blood cells per high power field. A flat plate of the abdomen showed no air under the diaphragm.

The patient was operated on immediately after admission.

DIFFERENTIAL DIAGNOSIS

DR ERNEST M. DALAND: This was an acute abdominal emergency, the patient coming in six hours after the onset of pain. We think immediately of the possibility of a pre-existing gastric lesion, such as an ulcer, but the first paragraph does not give a very clear picture of such a condition. There was no definite relation of his symptoms to meals, and apparently the pain was not relieved by food but was relieved by cream of tartar, which is acid potassium tartrate. I do not know whether that is used in the same way as soda is, and I do not know the significance of relief by cream of tartar.

We are told that this man was thin, restless, extremely ill, groaning and complaining of severe pain. The abdomen was extremely rigid but not distended. The symptoms seem to have been centered around the umbilicus and somewhat on the right side. In this region, we think of abnormalities of the gall bladder, duodenum and pancreas. I think the sudden onset rules out perforation of the gall bladder. The gall bladder does not perforate unless it is gangrenous, and this was a little too rapid for a gall bladder to become gangrenous and rupture. There may have been a diverticulum of the duodenum that had ruptured. The possibility of carcinoma of the stomach must be considered. However, the symptoms went back five years, and there is no evidence that they had particularly changed during the last few months. Perforation of a carcinoma of the stomach is a very rare condition, although it does occur and simulates a perforated ulcer. Mesenteric thrombosis should be considered. The rigidity was quite generalized, although a little more marked on the right. This is a rather rapid history for mesenteric thrombosis, however. The usual story in this condition is a warning sign of mild pain at the time the thrombosis starts,—an interval of a few hours,—and then sudden violent pain due to change in circulation. Acute pancreatitis, I think, can be ruled out on the same basis. This is too rapid an onset to go on to perforation of the pancreatic capsule. Obviously, the patient did have some type of perforation.

I should like to know whether this patient had any sugar in his urine, because diabetic coma can

simulate a perforated gastric ulcer. I once was called to the Emergency Ward to see a patient with an acute abdominal history. The story seemed to be perfectly typical of perforated ulcer. I was told that the patient was in the third room, went down and examined him, put my hand on his belly and said, "This is a typical belly of a ruptured ulcer." Then someone said: "This is the wrong patient. This patient has diabetic coma. Your patient is in the next room." I have never forgotten it.

DR. TRACY B. MALLORY: The qualitative test for sugar was positive; it was not quantitated.

DR. DALAND: I doubt very much if this was diabetic coma. The sudden onset rules it out, but it should be thought of.

My opinion is that this patient had a perforated peptic ulcer, even though the history is not typical. The clinical finding of extreme rigidity in an extremely ill patient to me means perforated peptic ulcer.

DR. MALLORY: I take it then, Dr. Daland, that you believe this patient should have been operated on immediately. Where would you make your incision?

DR. DALAND: I should make a right upper rectus-splitting incision.

DR. MALLORY: That was done on this patient, and a perfectly normal stomach and duodenum were found. With further exploration, pus appeared to well up from the left lower quadrant.

Would you care to speculate on what you might have done at that point?

DR. DALAND: I think I should have made another incision.

CLINICAL DIAGNOSIS

Perforated peptic ulcer.

DR. DALAND'S DIAGNOSIS

Perforated peptic ulcer.

ANATOMICAL DIAGNOSIS

Perforated carcinoma of sigmoid.

PATHOLOGICAL DISCUSSION

DR. MALLORY: A second incision was made in the lower left rectus muscle, and an obvious carcinoma of the sigmoid was found with a perforation through it. The sigmoid was then exteriorized through the abdominal wound. There was, of course, an obvious general peritonitis. The patient survived only a few days.

At the time of autopsy, nothing further was found that would account for any of the symptoms. It was quite clear that the spontaneous per-

foration of the sigmoidal carcinoma was the source of the immediate symptoms.

DR. D. N. SWEENEY, JR.: It is of some interest that after the patient's death his wife admitted that she had given him three enemas, which obviously passed through the perforation and thus aided the rapid generalization of the peritonitis.

CASE 28382

PRESENTATION OF CASE

A forty-year-old secretary entered the hospital complaining of fatigue and shortness of breath.

The patient felt perfectly well until she was nine years of age, when, during the course of a summer, without symptoms and without pain, she developed a crooked back. For several years thereafter, she performed daily orthopedic exercises without apparent benefit, and the deformity seemed to progress. Various overcorrecting braces were applied, but these were very uncomfortable and gave no relief. For many years, the patient had worn a supporting brace during the day; this was comfortable and relieved fatigue.

Ever since the deformity appeared, that is, for the previous thirty years, the patient had suffered from dyspnea and fatigue on exertion, which tended to progress very slowly. Two years before admission, during a period of unusual emotional and physical strain, the patient became very nervous and suffered from extreme fatigue and dyspnea on the slightest exertion, the whole culminating in an almost complete breakdown one year before entry. She took a long holiday, and very gradually her strength returned, so that six months before admission she resumed secretarial work. Soon, however, weakness and fatigue reappeared and reached a point where the hands trembled during work and she had to rest several times during the short walk home, sometimes fell asleep at the evening meal, and seemed dazed on being awakened.

The patient had occasionally noticed palpitation but no dizziness, fainting, edema, cyanosis, chills, fever, cough or loss of weight. Although shortness of breath appeared on the slightest exertion, it was not present during rest, and she was most comfortable when lying perfectly flat on her back.

The family history was irrelevant. The patient had suffered from the usual childhood diseases; there was no history of poliomyelitis, tuberculosis or rheumatic fever. An ovarian cyst had been removed twelve years before admission, and the patient stated that she had had a "heart murmur" for many years.

On examination, the patient was frail, with rapid, shallow breathing and deep cyanosis of the lips and fingers. Distended veins were present in the right neck, but not on the left, and no pulsation was visible. In the spine, there was an extreme dorsal scoliosis, with the convexity to the right, a moderate lower dorsal lordosis and an upper dorsal kyphosis. The sternum was just to the right of the midline, and a slight depression was present in the right chest anteriorly and the left chest posteriorly. Chest expansion was poor, but the lungs were clear.

Cardiac dullness extended into the entire left axilla and about 4 cm. to the right of the mid-sternal line. An impulse was felt in the left chest posteriorly, the rate varied between 70 and 103, and there were occasional extrasystoles. A loud harsh systolic murmur was heard throughout the left axilla and to a lesser extent in the aortic area. The pulmonic second sound was loud, and both sounds were rasping in this area. The abdomen was tense, with percussion dullness in the right upper quadrant to the umbilicus and in the left upper quadrant to three fingers below the costal margin; no organs could be felt. There was no peripheral edema. Examination of the nervous system was negative.

The blood pressure was 125 systolic, 80 diastolic. The temperature was 99.5°F., the pulse 90, and the respirations 20 to 30.

The urine showed a ++ test for albumin. The blood revealed a red-cell count of 5,900,000 with a hemoglobin of 14.5 gm. (photoelectric-cell technique), and a white-cell count of 6700.

An electrocardiogram showed normal rhythm, with sinus arrhythmia in Lead 2 and a PR interval of 0.14 second. There were low voltage in Lead 1, a low R₄, an elevated ST₄ and an inverted T₄. There was a tendency to right-axis deviation.

The patient was digitalized rapidly and that night became irrational, restless, frightened and suddenly more cyanotic, with marked venous engorgement. Tourniquets were applied to the extremities, an oxygen tent used, and later, the orthopedic brace was fitted on. The next day, the patient's pulse was stronger, the color better and the respirations deeper, although she had lapsed into coma with deep cyanosis and paroxysms of muscle twitching in her arms and legs; a 500-cc. venesection had no apparent effect. On the third hospital day, there was some improvement, and the patient became coherent; on the following day, however, she again became comatose. An electrocardiogram showed no essential change since the previous tracing. Death occurred on the fifth

hospital day. At no time were there abnormal neurologic signs or peripheral edema.

DIFFERENTIAL DIAGNOSIS

DR. ROBERT E. GLENDY: This history, in brief, is that of a middle-aged woman with a severe dorsal spinal deformity of thirty years' duration, long-standing progressive dyspnea and fatigue on exertion, manifest cardiac enlargement and, finally, an unusual train of symptoms, including extreme dyspnea, cyanosis, unilateral venous engorgement in the neck, accentuation of the pulmonic second sound, poor chest expansion but clear lungs, some ascites but no peripheral edema, and a normal blood pressure. It was the progression of these pulmonary and cardiovascular signs and symptoms that resulted in her death. The problem therefore resolves itself into one of establishing the underlying factors that would produce such a picture.

At the age of nine, the patient developed a crooked back, which was painless and without symptoms except for the dyspnea and fatigue that attended the deformity almost from the outset. The chief curvature of the spine is described as one of extreme dorsal scoliosis. Lateral curvature of the spine may be the result of muscular unbalance, congenital defects of the vertebrae, irregular growth of the vertebral bodies, as in rickets, and destructive lesions causing lateral collapse of the vertebra. Just which of these factors was responsible in this case is not clear. The age at onset rules out a congenital defect. There was no paralysis or other neurologic abnormality that would point to such conditions as spastic paralysis and syringomyelia. No mention is made of empyema or thoracic surgery, which sometimes produce thoracic deformities. The irrelevant past and family histories, the absence of pain and the type of deformity are against the possibility of a tuberculous spine. This leaves poliomyelitis or some disturbance in the growth of the vertebral bodies as the remaining possibilities. There is no history of the former, but either one could produce such a deformity of the spine, and for the purposes of this discussion, no further conjecture seems necessary. The deformity, running true to form, increased rapidly during puberty, in spite of orthopedic treatment, and because of secondary changes in the thorax undoubtedly caused cramping and distortion of the lungs, heart and great vessels.

Before developing this idea further, however, let us consider the history and findings for other cardiovascular etiologic relations. There was no

history of rheumatic infection, and yet the patient had a harsh systolic murmur, heard best in the left axilla, which could have been due to valvular heart disease (mitral regurgitation). The strongest argument against this is the fact that she had symptoms pointing to a poor cardiac reserve for many years—in fact, from the very time that the spinal deformity appeared. This is certainly not the usual history of mitral regurgitation, which, as a rule, acts as a benign, well-compensated lesion for long periods before signs of myocardial insufficiency appear. My guess is that no organic cause for this murmur will be demonstrated at autopsy other than dilatation of the heart. The fact that the patient was perfectly well during her early childhood is very much against any significant congenital heart lesion. From the evidence presented, hypertension and coronary disease deserve no serious consideration as underlying factors, nor does syphilis. Therefore, in the absence of any of the usual etiologic factors in heart disease, I am forced to the conclusion that the distortion of the thoracic viscera secondary to the spinal deformity was the underlying cause of the trouble. Occurring so early in life, the thoracic deformity must certainly have impaired the development of the lungs. This would account for the habitual dyspnea for so many years.

The entire picture seems to conform completely with the syndrome described by Chapman, Dill and Graybiel,* which occurs in persons afflicted with severe deformities of the chest and spine and has been called by them "pulmonocardiac failure." The most striking feature of their studies on a group of patients with scoliosis from the Orthopedic Department of this hospital was the absolute and relative reduction in lung volume. Additional evidence that the chief effect of this syndrome is on the lungs was found in the clinical facts that respiratory depressants, pulmonary infection, cramped position or anything that further reduces pulmonary function may lead to attacks that resemble sudden heart failure. Their account of the symptoms and signs of this condition include habitual dyspnea, persistently rapid heart rate, accentuation of the pulmonic second sound, right-sided cardiac enlargement (by fluoroscopy), occasional right-axis deviation in the electrocardiogram and, as the disease progresses, attacks of paroxysmal dyspnea, great weakness and fainting, which mark the onset of pulmonocardiac failure. Once these severe symptoms appear, the interval before death is usually short.

*Chapman, E. M., Dill, D. B., and Graybiel, A. The decrease in functional capacity of the lungs and heart resulting from deformities of the chest: pulmonocardiac failure. *Medicine* 18:167-202, 1939.

Without enumerating each sign and symptom again, I believe that this patient followed the clinical pattern outlined above quite closely. The detection of cardiac enlargement in the presence of severe thoracic deformity is difficult, but, judging from the area of cardiac dullness described in this case, I should predict that post-mortem examination will show enlargement of the heart, particularly the right ventricle. In view of the age at the onset of the chest deformity, it is likely that the lungs were poorly developed and entirely inadequate for adult development. This decrease in actual lung substance may also be attended by areas of atelectasis or emphysema, or both. One might anticipate an infection in the lungs that acted as an additional precipitating factor to the cardiac failure, but nothing is recorded in the history to support this idea except slight fever (99.5°F.) on admission. The presence of unilateral (right) venous engorgement in the neck and ascites suggests that the distortion of the heart and great vessels may have been so great as to interfere with the drainage of both the superior and inferior vena cavae.

CLINICAL DIAGNOSES

Pulmonocardiac failure.
Scoliosis.

DR. GLENDY'S DIAGNOSES

Pulmonocardiac failure, secondary to cramping and distortion of thoracic viscera from severe dorsal scoliosis of obscure etiology (poliomyelitis or growth disturbance in vertebrae).
Cardiac hypertrophy, predominantly right ventricular.
Maldevelopment of lungs.

ANATOMICAL DIAGNOSES

Kyphoscoliosis, right dorsal, extreme.
Degeneration of anterior horn cells of spinal cord.
Cor pulmonale, slight.
Pulmonary hypoplasia.
Acute passive congestion.

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: This case is a very characteristic example, as Dr. Glendy has pointed out, of so-called "pulmonocardiac failure" based on spinal deformity. This syndrome, which has been well recognized in Europe for many years, received very little attention in this country until the studies of Chapman, Dill and Graybiel. These

studies were important not only in calling attention to this by no means rare condition but also in demonstrating that the very low reserve of these patients is due to a marked reduction in all components of the vital capacity. Although the symptoms usually suggest right-sided heart failure, the degree of cardiac abnormality is usually not very great.

In this patient, the right auricle was greatly dilated, and the right ventricle a little dilated and also slightly but definitely hypertrophied. The left side of the heart, the valves and the coronary arteries were entirely normal. The viscera were acutely congested, but there was no evidence of severe and long-standing passive congestion, such as one might expect in the cor pulmonale of Ayerza's disease. The lungs were of normal

weight but small volume. The right lower lobe, in particular, was a mere shell, 5 to 10 mm. in thickness. All lobes, however, were aerated, and there were no foci of either atelectasis or emphysema.

The cause of the scoliosis remains in doubt. There was no disease of the vertebrae, either congenital or acquired, but the spinal cord showed extensive loss of ganglion cells. I should have accepted this as evidence of old poliomyelitis, but Dr. Charles S. Kubik believed that the findings were not sufficiently typical and that some other neurologic disorder must be assumed. He refused, however, to commit himself regarding what this might be. Unfortunately, we did not have permission to examine the entire central nervous system.

"BUSINESS AS USUAL"

THE proprietor of one of Boston's most respectable bars (although associated in no official way with the legal profession), a spectator of man's progress onward and downward, has been credited with the observation that our drinking habits have changed. Since the immensity of our war problem has impressed itself on us, we have turned, paradoxically enough, to sober drinking. We sip our liquor seriously, even sadly. As our spirits go down, our spirits go down: this, at least, has been the judgment of one with every opportunity for an analysis of the situation.

It is true that the task to which we have set ourselves has touched the lives and is affecting the

destinies of everyone in our country, to put it provincially. Many have dedicated their lives entirely to it, and not a few have already given their lives for it; many have as yet had little of the burden to bear, although the majority will be ready when each one's way is clearly shown. Our thoughts are constantly colored by the changed atmosphere in which we live, the altered tenor of our ways, the anxiety of the days through which we are passing and the uncertainty of the relentless future, when that presents its bill.

We have been told repeatedly, by the authorities to whom we have delegated the regulation of our affairs, that we must turn completely from our sinful ways, "or else . . .," that we must give ourselves entirely to the war effort, that frivolity is finished, profit is outlawed and "business as usual" is through. All of which is good, sound, wholesome advice, provided there does not appear so much scribbling on the wall that he who runs will have to stop and lose the race while he reads it.

Our leaders, of course, are right, and they are doing a very serious and important job in a very serious and important manner. To a certain degree, — and we must resign ourselves to our American tendency to overdo everything, — we must be treated like children. We must accept not only direction but chiding and nagging, for that is the parent's anxious way.

We must also remember, however, that too great an emotional concentration on a heroic task may have its paralyzing effect as well. There are still other things to do besides concentrating on a supreme effort and fumbling with a radio dial. The tension of the concentrated effort has its natural reaction in a temptation to dispersal of our energies in all other directions. What is left of our maligned "business as usual" may seem so trite that a determination equivalent to heroism is required to get at it and get it done, but the stabilizing value of what can decently remain of it must not be neglected even in the glare that comes from the forge of Vulcan. The fundamental sanity of also keeping our home fires burning, despite domestic fuel reduction, should not be lost sight of entirely.

CONSTITUTIONAL INADEQUACY

CONSTITUTIONAL inadequacy may become a new diagnosis to be added to the already overcrowded nomenclature. Alvarez* has recently called attention to the many patients who are "always weak and tired and full of puns and always getting sick in one way or another." They have numerous operations and repeated treatments for various organs of the body, and still do not get well. Several different types of this syndrome are outlined. Reference is made to asthenic persons who cannot stand much work, excitement or loss of rest, to the women who are troubled with their pelvic organs and, perhaps, with their glands of internal secretion, to those who have a poor resistance to infections of all kinds and a poor ability to recover from them, to those who become senile early in life, to persons whose symptoms are mainly those of an irritable colon, and to those who complain of "nervousness," who are worrying and who are continually running to a physician for this or that minor ailment. Of course, there are many frail, sickly looking persons who have sufficient energy to perform their daily work, or perhaps to perform outstanding feats in the face of all sorts of illness and discouragement, they are not inadequate in any sense of the word.

It is a universal desire to leave no stone unturned in the search for health by all the new developments of modern medicine. This inadequacy, however, is to be suspected whenever disabilities of various kinds and feelings of great fatigue have been present for years without bringing disaster, whenever the severity of the symptoms is out of all proportion to the disturbances found on examination and whenever the aches and pains are scattered too widely to be explained on the basis of any one lesion. It seems likely that the fundamental cause is in the nervous system, but whether a separate label beyond those already used is necessary for this inadequate group is a moot point.

In the past, numerous miracles have been wrought by the removal of foci of infections and by the use of hormones, vitamins and other newly discovered therapeutic agents, but many failures are recorded and a large amount of unnecessary treatment has been given. This diagnosis, therefore, must be used with discrimination. It is imperative that the physician, especially in borderline cases, make a careful estimate whether the findings in a given patient warrant operative interference or a long course of treatment and whether there is a reasonable probability of bringing about real health. A full knowledge of this syndrome and its use in suitable cases will undoubtedly lead to the avoidance of unnecessary therapy. But, if the diagnosis is employed, physicians must adopt a technic of explaining the situation to their patients in such a way that the latter will accept [the] verdict of constitutional inadequacy without annoyance or rebellion and will decide to mend their bad psychic ways, to hoard their energies and to live within their limited means of strength.

MEDICAL EPONYM

RIGGS'S DISEASE

A paper read before the American Academy of Dental Surgery in New York on October 20, 1875, by John W. Riggs (1810-1885), M.D., F.A.A., D.S., of Hartford, Connecticut, entitled "Suppurative Inflammation of the Gums and Absorption of the Gums and Alveola [*sic*] Process," has served to attach his name to the condition of pyorrhea. This appeared in the *Pennsylvania Journal of Dental Science* (3:99-104, 1876). A portion of the text follows:

This disease is called by many the disease of old age but at the present day we find the middle aged, and even the young, affected by it. One by one the teeth become loose from loss of bony support and are plucked out as an intolerable annoyance. If the inflammatory action be great and involve most or all the gum embracing the teeth pus tinged with blood exudes from around the necks of the teeth on the slightest pressure of the lips or tongue, or in mastication. The oral secretions become vitiated, present a viscid or sanious character, very abundant in quantity during the day, but much more so in the recumbent position of sleep. If the patient reposes on his side these exudations flow out of the corner of the mouth

*Alvarez, W. C. Constitutional inadequacy. *J. A. M. A.* 119: 80-83, 1942.

over the pillow and present in the morning a dried, yellow discoloration, often tinged with blood and covering a space as large as one's hand. If the patient reclines on his back the diseased mass flows back into the fauces and is unconsciously swallowed, then to work a greater mischief. . . . None but the most vigorous constitutions can withstand this type of disease.

R. W. B.

MASSACHUSETTS MEDICAL SOCIETY

STATED MEETING OF THE COUNCIL

A stated meeting of the Council of the Massachusetts Medical Society will be held in John Ware Hall, Boston Medical Library, 8 Fenway, Boston, on Wednesday, October 7, 1942, at 10:30 a.m.

Business:

1. Call to order at 10:30 a.m.
2. Presentation of record of meeting held May 25 and 26, 1942. (Published in the *New England Journal of Medicine*, issue of June 25, 1942.)
3. Reports of standing and special committees.
4. Appointment of an auditing committee.
5. Fill any vacancies in the offices of the Society.
6. Such other business as may lawfully come before this meeting.

MICHAEL A. TIGHE, M.D., *Secretary*

IMPORTANT REPORTS TO BE CONSIDERED BY THE COUNCIL

SURVEY OF STATE-AIDED CANCER CLINICS

At your request, I have made a survey of the state-aided cancer clinics and beg to submit the following report:

I have visited each clinic, with one exception, during the spring and summer and have also attended most of them previously. Of the one clinic not visited recently, I have some knowledge and have received reports from men who have conducted their teaching clinics.

It is difficult to determine the value of the cancer clinics alone, for they represent only part of the state cancer-control program. There are twenty-three consultation clinics, including those connected with the state cancer hospitals at Pondville and Westfield. The two hospital clinics are excellent in every way and will not be considered.

In 1941, 1782 new cases of cancer were seen at the clinics. This is estimated to be 8 per cent of the patients with cancer living in Massachusetts in a year. At first glance, this seems a small percentage, but it is probable that in most cases the remaining patients are receiving adequate care from their own physicians, are seen in private consultation, or have consulted the tumor clinics maintained by many of the larger hospitals. Most of the patients seen in the clinics are impecunious, although in certain localities, notably Beverly, Lowell and Lynn, it is not unusual for physicians to refer their well-to-do patients for consultation.

The statistical data of the clinics for the year 1941 are shown in Table 1; 5117 new patients consulted the clinics, of whom 1782, or 35 per cent, had cancer. The total attendance was 26,118.

Organization

The consultation cancer clinic is generally accepted as being one of the best methods of controlling the disease. Clinics similar to those in Massachusetts have been set up in the rest of the country and in general follow the rules laid down for cancer clinics by the American College of Surgeons. Group consultation is advocated, all patients being seen by a clinician, a radiologist and a pathologist, but it is impossible to conform to this requirement in certain communities. The best organized clinics consist of a permanent committee, one of whom is present at each clinic, supplemented by a rotating staff composed of the surgeons connected with the local hospital. This setup obtains in only a few clinics, however, but should be more generally adopted. Each clinic has attached to it a full-time or part-time social worker and a secretary.

Functions

The function of the clinics is fivefold: to furnish consultation; to furnish treatment at the state cancer hospitals when it is indicated and requested; to follow up treated cases through the social-service worker, to determine the results of treatment, and to advise further procedures if necessary; to educate the public in regard to cancer through the knowledge that such a clinic functions in their community; and to educate the practitioners in the community in the early diagnosis and modern treatment of cancer through consultations and teaching clinics.

Finances

The clinics are maintained at a considerable expense. The budget for the year 1942 is \$28,000, which is a cut from previous years. About half is designated for salaries for social workers (\$14,260 in 1941). The appropriations are placed in the hands of the committee in charge of the individual clinic, to be expended as in their judgment seems best. The other items of expense vary greatly in the different clinics for no obvious reason. One clinic has a charge of \$409.70 for "traveling expenses," whereas only two others have a charge under this heading, and both are under \$10. I question the need of this expenditure. The Boston Dispensary clinic has a charge of \$1125.20 for "diagnostic procedures" on 573 patients, whereas charges under the same heading in Lynn are \$41.60 for 560 patients. The Lynn clinic is as efficient as any in the State. This suggests on the one hand that the hospital, or patient, has assumed some of the expense of these procedures and, on the other, that the facilities for free diagnosis of patients with suspected cancer may be abused. The Beverly clinic is maintained at a cost of \$0.67 a patient visit, whereas the cost per visit in Pittsfield is \$6.61. Undoubtedly, economies could be practiced in many of the clinics, but this is the responsibility of the committee of physicians in charge, for the Department of Public Health has chosen to work through the medical profession. It may be said that if only 1 life in 8 of the 1782 new patients with cancer disease consulting the clinics in a year is saved by this consultation, a life is worth \$125 in round figures.

The expenses incurred by the clinics for 1941 are given in Table 2.

Teaching Clinics

Out-of-town physicians are invited to hold clinics and give a talk on some special subject two or three times during the year at many of the clinics. Notices of these talks are sent to the physicians in the neighborhood.

These teaching clinics are usually very well attended and, I believe, have an educational value

SUMMARY OF CLINICS

Beverly A well-organized and well-run clinic. The figures of attendance suggest a falling off in the number of cases seen, but I do not believe they give an accurate idea of the work. There are facilities for diagnosis and

nosis and all forms of treatment. One hundred and fifty new patients were seen in 1941, of whom 76 had cancer. This is 40 per cent less than the number of cases seen in 1940. Two teaching clinics were held in 1941. Unit cost per visit is \$1.98. The budget is \$3000. It is necessary to continue this clinic.

Boston Dispensary This is a large, active, well-run clinic. There has been a slight falling off in the number

all forms of treatment. Sixty-nine new patients were seen in 1941, of whom 18 had cancer. Unit cost per visit is \$0.67 (the smallest of any clinic). The budget is \$250. This clinic should be continued.

Beth Israel Hospital, Boston This is a large clinic conducted by a very competent radiologist, a pathologist be

of new cases seen in the past two years. Of 429 new patients referred to the clinic in 1941, 132 had cancer. There are facilities for diagnosis only—none for surgical or high voltage x-ray treatment. It is difficult to separate the patients seeking advice in the state-aided clinic from those referred from the general outpatient clinic. There

Totals	\$14260.25	\$1994.02	\$ 674.49	\$2867.59	\$1 81.52	\$171.58	\$14 8.03	\$663.62

ing available at all times. The hospital has only fifty to sixty ward beds, the remainder of the beds being reserved for private patients. There are facilities for diag-

is a charge of \$1125.20 for "diagnostic procedures" for 575 patients that might be compared with Lynn which has a charge under this heading of \$41.60 for 560 pa-

tients. Unit cost is \$1.62. The budget is \$3500. This clinic should be continued.

Brockton. This is a relatively active clinic that does not function in a very satisfactory manner, probably because of local conditions. Little interest appears to be taken in the clinic by the practitioners in the city. It is held at the Brockton Hospital, and certain of the physicians in charge of the clinic are not on the staff of that hospital and their authority is therefore limited. There are facilities for diagnosis and surgical treatment only. Patients requiring radiation treatment or special investigation are referred to Pondville Hospital. One hundred and thirty-five new patients were seen in 1941, of whom 60 had cancer. This is about half the number of cases of cancer seen in 1935. There were four teaching clinics held during this year. Considering the population of the city, the clinic should be larger. Unit cost is \$4.33. The budget is \$2000. Brockton is relatively close to the Pondville Hospital, and unless more interest is shown by the medical profession of Brockton, the advisability of discontinuing the clinic should be considered.

Fall River. This is an active clinic under the charge of a committee one member of which is usually present on each clinic day. On the day of my visit, five visiting physicians were present. There are facilities for surgical consultation and radiologic and surgical treatment. Besides the general clinic, there is a special gynecologic clinic. Four teaching clinics were held in 1941, with a large attendance. One hundred and forty-two new patients were seen in 1941, of whom 54 had cancer. On the day of my visit, 19 patients were examined. This is a well-managed, active clinic, considering the fact that there are three hospitals in Fall River. Unit cost per visit is \$1.13. The budget is \$800. This clinic should be continued.

Fitchburg. This is a relatively active clinic conducted by a permanent staff; a surgeon and a radiologist are usually present, but no pathologist is attached to the hospital. There are facilities for consultation and radiologic treatment. The clinic is somewhat hampered, for many of the younger men have entered the service. On the day of my visit, there were 10 patients. In 1941, 44 new patients were examined at the clinic, of whom 15 had cancer. Three teaching clinics were held in 1941. Unit cost per visit is \$1.45. The budget is \$500. This clinic should be continued.

Gardner. This is a well-organized and well-run clinic. All the practitioners in the vicinity seem interested. Dr. Pierce, former director, is now in service, but his place has been taken by Dr. Thompson. Consultation and facilities for surgical and radiation treatment are offered. Fifty new patients were seen in 1941, of whom 17 had cancer. Five teaching clinics were held during that year. Unit cost per visit is \$2.95. The budget is \$600. The clinic should be continued.

Gloucester. This is a well-organized clinic administered by a permanent committee and a rotating staff. It offers consultation and facilities for surgical treatment only. No pathologist or radiologist is available. The clinic is small, but the local men apparently take considerable interest in it. Forty-four new patients were seen in 1941, of whom 6 had cancer. Three teaching clinics were held during that year. Unit cost per visit is \$2.33. The budget is \$200. The clinic should be continued.

Greenfield. This clinic was discontinued in 1933, was reopened in 1935, and was again discontinued in 1941. A

committee of the Hampden County Medical Society then drew up recommendations regarding the conduct of the clinic, and it was reopened in 1942. The chairman of the committee, I understand, has attended only one clinic during the year. On the day of my visit, no member of the committee was present. The city apparently wants the clinic, but little interest is taken in it. There are facilities for consultation and surgical treatment only. Thirty-three new patients were seen in 1941, of whom 12 had cancer. Unit cost per visit is \$4.50. The budget is \$600. If the physicians of the locality are not willing to support it in a more active manner, this clinic should be discontinued.

Hyannis. This clinic is practically administered by one man and not by a committee. The physicians in the locality are not co-operative. How much of this is due to the manner in which the clinic is conducted, it is impossible to say. The clinic should be managed by a committee, but it is difficult to find men in this community particularly interested in or having a knowledge of cancer. The budget is large, particularly certain items in the expense account (Table 2). Twenty-four new patients were seen in 1941, of whom 13 had cancer. Unit cost per visit is \$4.28. The budget is \$700. Several teaching clinics were held, which were well attended. This clinic does not function in a satisfactory manner, and I should advise discontinuance except for the fact of its geographical situation, for it serves the entire Cape Cod area. It might well be reorganized.

Lowell. This is an excellent and well-organized, well-run clinic in charge of a permanent committee, one of whom is always present, assisted by a rotating staff. Much interest is shown by the physicians and patients. Consultation and treatment facilities, for both surgery and radiation, are available. One hundred and fifty-six new patients were seen in 1941, of whom 41 had cancer. Unit cost per visit is \$1.74. The budget is \$1500. This clinic should be continued.

Lawrence. This is an active clinic in which much interest is shown by the local profession. A pathologist and a radiologist are available if not present at each clinic, as well as a clinician. There are facilities for consultation as well as for radiation and surgical treatment. Five teaching clinics were held in 1941. One hundred and twenty-nine new patients were seen in 1941, of whom 50 had cancer. Unit cost per visit is \$3.22. The budget is \$1700. The clinic should be encouraged.

Lynn. This is an active, well-run general clinic as well as a special genitourinary and gynecologic clinic. It has the support of the local physicians, many of whom refer their well-to-do patients for consultation. There are facilities for consultation as well as for surgical and x-ray treatment. Two hundred and forty-nine new patients were seen in 1941, of whom 122 had cancer. Unit cost per visit is \$2.33. The budget is \$3000. The clinic should be continued.

New Bedford. This is a good setup and, on the whole, a well-run clinic. A full-time radiologist and surgeon are in attendance. There is consultation, surgical and radiation service. The patients are almost entirely from New Bedford — rarely from the surrounding towns. A surgeon and a radiologist are present at every clinic. Many of the younger men who formerly attended the clinics are now in service. One hundred and sixty-six new patients were seen in 1941, of whom 69 had cancer. Unit cost

per visit is \$2.37 The budget is \$7000 This clinic should be continued

Newburyport This clinic is not satisfactory The professional standards in Newburyport are as high as those in any other community, but there is no surgeon or radiologist in the city or any physician with special training in the treatment of cancer Little interest is taken in the clinic by the local men Cancer cases requiring consultation are sent either to Boston or the Pondville Hospital, or private consultation is obtained Twenty five new patients were seen in 1941, of whom 6 had cancer Unit cost per visit is \$3.16 The budget is \$300 I suggest that this clinic be discontinued

North Adams This is a small clinic in a relatively small community, but the local medical profession take considerable interest in it and are attempting to build it up Consultation and facilities for surgical treatment only are offered Patients requiring special examinations or radiation treatment are referred to the Westfield Sanatorium Seven new patients were seen in 1941, of whom 4 had cancer Unit cost per visit is \$4.78 The budget is \$400 I believe this clinic should be encouraged and supported

Pittsfield This clinic is unsatisfactory It is in charge of a committee but practically administered by one man who takes considerable interest in it Although Pittsfield is geographically the center of Berkshire County the clinic is not patronized by the physicians in the district, who generally refer cases to either Westfield or Albany Of 42 cancer patients from Berkshire County seen at the state aided clinics in 1941, only 2 were seen first in this clinic There were no patients in the clinic the day of my visit One teaching clinic was held in 1941 There are facilities for consultation and surgical treatment only Ten new patients were seen in 1941, of whom 2 had cancer Unit cost per visit is \$6.61 (the highest of any clinic) The budget is \$300 I suggest that this clinic be discontinued or entirely reorganized The Department of Public Health is investigating the situation

Pondville This is an excellently run and administered general hospital, with an outpatient clinic for the diagnosis and treatment of cancer The clinic and hospital offer all forms of treatment The hospital is handicapped at present by lack of nurses The staff is permanent, and special clinics are held One thousand five hundred and three new patients were seen in the outpatient department in 1941, 515 of whom had cancer There were 9153 outpatient visits The clinic and hospital should be supported and encouraged

Quincy This is a small clinic in which little interest is taken by local men, with the exception of the pathologist Patients on whom consultation is desired are usually referred directly to Boston, and the clinic is not patronized by the surrounding towns The staff is rotating, but only one man was present the day of my visit Eighteen new patients were seen in 1941, of whom 3 had cancer Unit cost per visit is \$1.08 The budget is \$75 I do not believe this clinic will ever increase on account of its proximity to Boston I suggest that it be discontinued

Salem This is an active, well run clinic Consultation services are offered, as well as radiologic and surgical treatment The committee in charge is active and several of the members are present at each clinic Many well-to-do patients are referred to it for consultation by local physicians Four teaching clinics were given in 1941 with an average attendance of 50 Unit cost per

visit is \$3.04 The budget is \$2100 One hundred and thirty nine new patients were seen in 1941, of whom 53 had cancer The clinic should be continued

Springfield This clinic is held in the Springfield Hospital but is served by a rotating staff from the hospital and the other two large hospitals in the city It does not give group-consultation service The chairman of the clinic was not in attendance on the day of my visit but was reached by telephone Many Springfield patients are referred directly to the Westfield Sanatorium Fifty five new patients were examined in 1941, of whom 9 had cancer Only 12 per cent of the cancer cases from Springfield are first seen at this clinic On the day of my visit, 4 patients were present, all follow up cases Unit cost per visit is \$1.25 The budget is \$2000 Considering the proximity of Springfield to Westfield (seven miles) and the lack of local interest, as well as for financial reasons I believe it would be well to discontinue this clinic and have all patients referred to the Westfield Sanatorium

Westfield Sanatorium This is a well run fifty bed cancer hospital equipped to care for and treat any form of cancer and having a large outpatient clinic as well All consultations are held in the general clinic on Wednesday, and patients are referred to the special clinics if necessary The staff is rotating, with a permanent surgeon in charge The clinic and hospital serve the western half of the State, and cases from the Pittsfield and North Adams districts are often referred here for consultation rather than to the local clinics For example, in 1941, of the 22 cases of cancer from the North Adams district, 18 were first seen at this clinic One thousand one hundred and ninety seven new patients were seen in 1941, of whom 564 had cancer The clinic and hospital should be continued

Worcester This clinic is held at the Memorial Hospital, the visiting men are in part from that hospital and in part from the other two large hospitals in the city This is apparently the condition that exists in many of the larger communities supporting more than one hospital The clinic interlocks with the follow up cancer clinic of the Memorial Hospital All forms of treatment are available Much interest is taken by several of the hospital staff and the clinic committee, and some research work is being done at the hospital One teaching clinic was held in 1941 Of 297 new patients seen in 1941, 67 had cancer Unit cost per visit is \$1.67 The budget is \$2700 This clinic should be continued

REMARKS AND CONCLUSIONS

The clinics must be considered a part of the cancer control campaign inaugurated by the Department of Public Health It is very difficult to evaluate the results of the work, but investigations are now being carried on in an attempt to determine what has been accomplished It may be said, however, that the mortality from cancer in the State rose steadily until 1935 but has remained stationary since that year, whereas deaths among women have shown a slight decrease This is not true in the remainder of the country, although the figures for New York State at the present time indicate a similar drop

As I see it, the conception of the consultation cancer clinics and the setup inaugurated by the Department of Public Health are excellent The clinics are for consultation only, and patients requiring treatment are referred to one of the two state hospitals Many patients, however, prefer to have the therapeutic procedure advised carried out at local hospitals if this is possible The success or

failure of the clinic depends entirely on the medical profession of the locality in which it is situated. It also depends on: the chairman of the committee, his energy and organizing and professional ability, and the confidence reposed in him by the physicians in the community; the co-operation of the practitioners in the district—unfortunately jealousies exist in certain communities; the interest of the local physicians; and the antagonism to "state medicine" felt by certain men, who, however, are willing to use the clinics for their impecunious patients.

The best setup of the clinics consists of a committee one of whom is present at every clinic assisted by a rotating visiting staff including a radiologist. This organization is impossible in certain centers, and the same standards cannot be demanded of a clinic situated in a small community, such as North Adams, as should prevail, for example, in Boston or Worcester. The activities of the cancer-control program and the clinics will probably be curtailed on account of the war. Many of the younger active men are in service, and the transportation of patients to the clinics is becoming increasingly difficult.

So far as finances are concerned, economies could probably be practiced in certain of the clinics, but this is the province of the local committees.

The teaching clinics are very well attended on the whole, and the advisability of holding them more frequently should be considered.

My opinion of the various clinics and my recommendations follow. It should be understood, however, that in judging the efficiency of the clinics the same criteria cannot be applied in every instance and that the classification between "excellent" and "good" is arbitrary.

APPROVED CLINICS

Excellent Clinics

Beverly

Fall River. This clinic is approved in spite of the facts that there are three large hospitals in the city and that the patients from the Truesdale Hospital are not seen in the clinic.

Gardner.

Lowell.

Lynn.

Pondville Hospital.

Salem.

Westfield Sanatorium.

Worcester.

Good Clinics

Boston—Beth Israel Hospital.

Boston Dispensary. This is a consultation clinic only.

Fitchburg.

Gloucester. This clinic is small, but much interest in it is being shown by the local medical profession.

Lawrence.

New Bedford.

North Adams. This is a very small clinic, but the committee is attempting to build it up.

CLINICS SUBJECT TO CRITICISM

Brockton. This appears to be an active clinic held at the Brockton Hospital, but certain of the men in charge of the clinic are not on the staff of that hospital; this fact hampers their efficiency. The attendance has fallen off half since 1935, and it does not appear to have the support of the local practitioners. It is apparently not uncommon for physicians to telephone the social worker, asking her if it is possible for a patient to be admitted

to the Pondville Hospital without passing through the clinic. It seems unfortunate to discontinue a clinic in as large a center as Brockton, but unless more interest is shown by the local members of the profession in the future, this should be considered and patients referred directly to Pondville Hospital, which is relatively near.

Greenfield. This clinic has been discontinued twice (in 1933 and 1941) since it was first opened. It was reopened in 1942, and recommendations for its conduct were drawn up by a committee appointed by the president of the Hampden District Medical Society. This committee was then discharged, and one to select the clinic appointed, consisting of one man from Greenfield, one from Montague and one from Shelburne Falls. These men are all busy and find it difficult to give up the time to attend the clinic. None were present on the day of my visit, but I finally interviewed the chairman in Montague. So little interest is shown that I believe this clinic should be again discontinued.

Hyannis. The clinic is administered by one person and is small, considering the size of the territory served. The budget is relatively large (Table 2). Considering its geographical situation, it is probably necessary to continue it, but it should be reorganized, if possible.

Newburyport. There are many excellent practitioners in the city, but no surgeon or radiologist and no one with a special interest in cancer. In cases of suspected cancer, private consultations are usually obtained. The clinic is small, serving 25 new patients in 1941, of whom 6 had cancer. The budget, however, is also small—\$300. I believe this clinic should be discontinued.

Pittsfield. This clinic, although situated in the center of Berkshire County, is not patronized by the local profession, who refer their patients directly to Westfield or Albany. Only 10 new patients were seen in 1941, and on the day of my visit there were no patients. Of the 42 patients with cancer from the Pittsfield district examined at the state clinics in 1941, 40 were first examined in Westfield. The unit cost per visit is higher than that in any other clinic—\$6.61. This clinic should be reorganized or discontinued. (The Department of Public Health is investigating the situation in Pittsfield at the present time.)

Quincy. This is a small clinic and is not patronized by the physicians in Quincy or the adjacent towns, who usually obtain a private consultation or refer their patients to one of the Boston clinics. Three new cases of cancer were seen at the clinic in 1941. I suggest that this clinic be discontinued. (Since the above was written the Department of Public Health has received a letter from the committee in charge of this clinic suggesting that it be discontinued.)

Springfield. There is a lack of interest shown by the physicians of the city in the clinic, and it does not appear to function in a satisfactory manner. Only 12 per cent of the cases of cancer from Springfield consulting the state cancer clinics are first seen in this clinic. Springfield is seven miles from the Westfield Sanatorium, and there are good transportation facilities. I believe the clinic should be discontinued.

CHANNING C. SIMMONS, M.D.

REPORT OF COMMITTEE ON CANCER

In accordance with the vote of the Council, requested by this committee in May, the President appointed Dr. Channing C. Simmons to investigate and report on the state-aided cancer clinics. This report has been presented to the secretary of the Society, and the Committee on

Cancer makes the following comments and recommendations based on it

The committee desires to commend the diligence, effort and thought that have gone into the preparation of Dr. Simmons's report. Only one with his long experience in the cancer field could grasp the many problems and assay the work that is being done

It gives great satisfaction to the committee to realize from this report the excellent work that is being done here. The State by the members of the Society in the field of cancer. The wholehearted co-operation of the medical profession with the Department of Public Health in this field has done much to make Massachusetts the leading state in cancer control

Several facts are apparent both from Dr. Simmons's report and from general experience

The mere existence of a cancer clinic in the community is useful, entirely apart from its own work, in bringing to the minds of hymen and physicians alike the problems connected with cancer, its diagnosis and its treatment. This indirect value of the state-aided cancer clinic to the community in which it is located is a factor that must be kept in mind in evaluating the work of any specific clinic and in weighing the advantage to the community as a whole of its continuance or discontinuance

The committee is well aware that at times the two state cancer hospitals, with their outpatient clinics, may appear to encroach on the field of nearby diagnostic cancer clinics. However, it is the opinion of this committee, as it is of the Department of Public Health and the staffs of the state cancer hospitals, that there should be no such encroachment, and every effort is being made to prevent it. The function of the cancer hospitals and their outpatient clinics is to supplement rather than to supplant the state-aided diagnostic clinics

With the difficult times ahead, when transportation becomes more and more a problem, the value of the regional distribution of the state-aided cancer clinics will become more and more apparent

To those members of the medical profession who have given their time and effort over the years to the carrying on of these clinics, the Society as a whole and every citizen of the State owe a debt of gratitude

Dr. Simmons's report is largely based on the viewpoint of service to patients. That, in the last analysis, is the yardstick by which the accomplishment of the clinics must be measured. However, other criteria must be employed: the indirect value of the clinic in the community, the role that it may play with the changing conditions of war, and the value that it may have under difficult conditions of transportation. The value of the clinic as a center of postgraduate education in cancer must also be given serious consideration

On the other hand, one must consider the increasing proportion of money flowing into the war effort and related fields, and the expenditures of the clinics must be carefully weighed against their utility to their communities and to the State

Considering Dr. Simmons's report as a whole in its relation to these facts, the Committee on Cancer presents to the Council the following recommendations

That the Council thank Dr. Simmons for his services

That it is advisable to suggest to the Department of Public Health the maintenance of existing clinics with the following exceptions: the state-aided clinics at Quincy and at Newburyport should be discontinued

That particular study be made of the clinics in Brockton, Greenfield, Pittsfield, Springfield and Hyannis to

determine whether they can be more active and of greater service to their communities (The physicians in these communities are now being interviewed to obtain their opinions of the clinics and their suggestions)

SHIELDS WARREN, MD, *Chairman*

COMMITTEE ON MATERNAL WELFARE

CASE HISTORY SEPTICEMIA AND DEATH FOLLOWING INTERNAL PODALIC VERSION

A twenty four year old primipara, who had had adequate and intelligent prenatal care, when about five months pregnant developed pyelitis, which subsided with treatment and did not recur. The past history was irrelevant. Labor began at term after spontaneous rupture of the membranes, and a forceps delivery was attempted after full dilatation. Since the position was posterior and the head could not be rotated, an internal podalic version was done. At the time of this procedure, the cord was not pulsating. The third stage of labor, after delivery of a stillborn infant, was uncomplicated. On the day after delivery, the temperature rose, and in spite of two transfusions and sulfanilamide therapy, the patient died of septicemia ten days after delivery. Several blood cultures were reported to be negative. Autopsy revealed post partum endometritis, with septicemia and early general peritonitis.

Comment It is unfortunate that the ineptness of the operator resulted in an unsuccessful forceps delivery. Undoubtedly, a trained obstetrician could have successfully delivered this patient without resorting to internal podalic version, which was performed after it was known that the fetus was not viable. It is probable, although not necessarily so, that the trauma of the internal podalic version was an element in the subsequent sepsis. When the fetal heart has ceased to pulsate, it is probably much better obstetrics to do a craniotomy than to resort to internal podalic version, a more difficult procedure.

This fatality occurred before sulfanilamide therapy had been intelligently worked out, and it quite possibly was not given so effectively then as it would be now. In spite of the fact that all blood cultures were reported to be negative, there is no evidence that a culture from the uterus was taken as a basis for sulfanilamide therapy. Sepsis may well occur without any operative procedure as a causative factor. It is too much to hope that chemotherapy will prevent such obstetric fatalities, but certainly intelligent chemotherapy combined with immune transfusions will reduce the rate very materially.

DEATHS

JACKSON — OLIVER H. JACKSON, M.D., of Fall River, died June 1. He was in his seventy-first year.

Dr. Jackson received his degree from Long Island College of Medicine in 1894. He was ophthalmologist at the Union and St. Anne hospitals and consulting ophthalmologist at the Fall River General Hospital. He was a member of the American Laryngological, Rhinological and Otological Society, the New England Ophthalmological Society and the New England Otological and Laryngological Society, and a fellow of the American College of Surgeons, the Massachusetts Medical Society and the American Medical Association.

O'TOOLE — JOHN L. O'TOOLE, M.D., of Haverhill, died September 2. He was in his sixty-fifth year.

Dr. O'Toole received his degree from Tufts College Medical School in 1908. He was medical examiner for the fourth district of Essex County, and a former member of the Massachusetts Medical Society and the American Medical Association.

WALSH — CHARLES J. WALSH, M.D., of Gilbertville, died September 6. He was in his eighty-fourth year.

A native of Barre, Dr. Walsh received his degree from College of Physicians and Surgeons, Baltimore, in 1893. He was a member of the Massachusetts Medical Society and the American Medical Association.

A brother and two sisters survive him.

WAR ACTIVITIES

PROCUREMENT AND ASSIGNMENT SERVICE

The Directing Board of the Procurement and Assignment Service for Physicians, Dentists, and Veterinarians, has recently adopted a formal resolution expressing its appreciation of the services rendered by Lieutenant Colonel Sam F. Seeley, who has been transferred to military duty. The text of the resolution is as follows:

The transfer of Lieutenant Colonel Sam F. Seeley from his connection with the Procurement and Assignment Service to active military duty causes a great loss. Lieutenant Colonel Seeley, who has acted as executive officer since the beginning of this service, has been transferred to military duty, which is in keeping with the policy recently adopted by the War Department. His training and experience with the Medical Corps of the Army in his professional capacity amply justify such a step.

The Directing Board of the Procurement and Assignment Service wishes to take this opportunity of expressing to the Surgeon General of the United States Army its very deep appreciation for the valuable service that Lieutenant Colonel Seeley has rendered during its period of organization and functions.

The Directing Board expresses to Lieutenant Colonel Seeley its deep appreciation for the great sacrifice that he has made in dislocating himself from actual military duty to serve with us in an executive capacity. He has been most unselfish, and has given unstintingly of his time, energy and patience in helping to solve many of the problems connected with the functioning of the

Procurement and Assignment Service. He has not only labored faithfully at our office in Washington, but he has traveled over the United States, making contact with many of his professional conferees and explaining to them the purpose for which the Procurement and Assignment Service was organized. His services have been most valuable and have helped to take us a long way in accomplishing the objectives for which the service was created.

The Directing Board expresses to Lieutenant Colonel Seeley its gratitude and thanks for his unselfish devotion to the organization of the Procurement and Assignment Service and wishes for him the greatest success in his new assignment.

MISCELLANY

PEPTIC-ULCER FILM AVAILABLE

The first complete motion-picture film on peptic ulcer, in color and with a sound track, is now available for showings before groups of physicians. The film is entitled "Peptic Ulcer" and was produced under the direction of the Department of Gastroenterology of the Lahey Clinic, Boston. The American College of Surgeons has awarded its seal of approval to the film. The running time is forty-five minutes, and the film covers a presentation of the following problems of peptic ulcer: pathogenesis, diagnosis, treatment, pathology, complications, including obstruction, hemorrhage and perforation, and gastric ulcer and jejunal-ulcer surgery.

Arrangements for a showing of the film before medical groups may be made by writing to the Professional Service Department, John Wyeth and Brother, Incorporated, Philadelphia, who will provide projection equipment, screen, film and operator, without charge.

NOTES

It is with great regret that the *Journal* records the death of Helen Matilda Bowers, wife of Dr. Walter P. Bowers, managing editor of the *Journal* for many years. Mrs. Bowers, who was eighty-five years old, had been in poor health for several years and had been confined to her home in Clinton.

The appointment of Dr. Roy D. Halloran, superintendent of the Metropolitan State Hospital, Waltham, Massachusetts, as chief of the Neuropsychiatric Division of the United States Army, with the rank of colonel, has recently been announced. Assigned to the Surgeon General's Office, Dr. Halloran will co-ordinate neuropsychiatric services in the Army, both in this country and overseas. He assumed his new duties on August 17.

Dr. Henry A. Christian, Hersey Professor of the Theory and Practice of Physic, Emeritus, has been invited by the President and Fellows of Harvard University to return to active duty to give clinical instruction; he has also been appointed visiting physician at the Beth Israel Hospital, Boston.

SULFONAMIDE THERAPY IN GONOCOCCAL INFECTION IN WOMEN AND CHILDREN*

Sulfanilamide, Sulfapyridine, Sulfathiazole and Sulfadiazine

FRED L. ADAIR, M.D.,[†] AND LUCILE R. HAC, Ph.D.[‡]

CHICAGO

THE value of sulfonamide therapy in gonococcal infection has been well established. Nevertheless, the present emergency has proved that gonorrhea is still a serious problem for the armed forces. According to data prepared by the office of the Surgeon General of the United States Army,¹ the year 1939 marked the lowest annual rate for admissions for venereal diseases; the rate dropped sharply in 1918 and 1919, gradually decreased all most year by year after 1922 and rose in 1940 with the increase in the Army, but was still below that of 1919. Some 60,000 selectees and volunteers were deferred because they showed evidence of venereal disease.

The increase in the total rate of venereal disease was largely due to a 50 per cent increase in the incidence of gonorrhea. There were more than 4 cases of gonorrhea to each case of syphilis. According to Rose, Kendell and Simpson²:

The antiquity, the inconspicuousness and the false sense of innocuousness all have combined to mask the real import of the havoc wrought by venereal diseases in the theaters of military and naval operations. In military and army parlance a casualty includes any officer or enlisted man rendered noncombatant as a result of death, wounds, illness, discharge, capture or desertion. During the first World War there were 100,000 more new cases of venereal diseases than there were war wounds in battle. Hence, the venereal infection ranks high in the production of casualties.

It is not practical to review the literature on the treatment of gonorrhea. Suffice it to say that the literature on the treatment in men is voluminous, the reports on women are fewer, and the results conflicting and confusing. It is gen-

erally conceded that professional prostitutes are the principal carriers of this infection, although the *Lancet*³ asserts that "even in country districts the vicious amateur forms a dangerous focus of disease and remains impervious to reason and education."

The part women play in the spread of this infection, therefore, makes it almost imperative that their treatment be accurately evaluated. It is essential to determine to what therapy women respond most readily, whether they harbor the organism over long periods with few or no symptoms, when they cease to be carriers and whether so-called "drug fast strains" are frequently produced.

It has been our purpose to study a sufficiently large series of women treated with each of the sulfonamides to be able to draw accurate conclusions concerning the best methods of diagnosis and treatment, and to determine the drug of choice and the necessary criteria of cure of this infection.

MATERIALS AND METHODS

In this study of 453 women and 80 children who received chemotherapy, all the patients were ambulatory.[§] Cure was based on routine cultures and smears. Four sulfonamides—sulfanilamide, sulfapyridine, sulfathiazole and sulfadiazine—were used. An attempt was made to assign the patients in rotation to the various drugs. Because sulfadiazine has been used only a short time, the series is smaller than those of the other drugs.

Classification of Patients

A total of 587 women received treatment, but 108 unco-operative patients were omitted because they could not be observed longer than one month. Of the remaining 453 patients, 145 became re-

*Most of the patients in this study were made available through Dr. H. N. Bundesen of the Chicago Board of Health and Drs. G. G. Taylor and D. K. Hibbs, of the Municipal Social Hygiene Clinic of Chicago.

†The sulfonamides used in this study were kindly furnished through the courtesy of the Department of Medical Research, Winthrop Chemical Company, New York City (sulfanilamide and sulfathiazole), Sterak and Company, Rahway, New Jersey (sulfapyridine) and Lederle Laboratories Incorporated, Pearl River, New York (sulfadiazine).

infected during the two-month observation period that followed therapy. We believe that these patients suffered two or more infections and have, therefore, designated *each infection* as a *case*, regardless of whether the patients received previous therapy. Accordingly, one patient might constitute two or more cases, making a total of 604 cases in all. Of these, 155 received sulfanilamide, 222 sulfapyridine, 166 sulfathiazole and 61 sulfadiazine.

Eighty children received a total of one hundred and five courses of treatment.* Fifty-four children received one course of therapy, 8 two courses,

on the isolation of the gonococcus in culture. The criteria of cure required that patients remain negative through two menstrual periods and two

postmenstrual provocative tests. Patients who did not menstruate were observed for two months, and received two provocative tests.

Smears and cultures were taken two or three times a week during treatment. After the first negative culture was obtained, smears and cultures were taken twice a week for the first month and at least once a week thereafter. They were also taken during and just following the menstrual period. The provocative test, which consisted of the application of 10 per cent silver nitrate to the cervix and 5 per cent silver nitrate to the urethra, was performed on the first or second postmenstrual day of each period, and cultures were taken on that day, and the first and fourth days subsequently. Children were checked during treatment and for the following month by cultures and smears taken twice weekly, then weekly for two months and monthly thereafter until they had been observed for a year; no provocative test was used. Blood for the determination of the drug concentration was taken once or twice during therapy.

RESULTS

Table 3 presents the results of treatment. Those cases designated as cures were observed through two negative menstrual periods followed by negative provocative tests. The failures occurred in cases from which evidence of reinfection could

not be elicited. Most of them had cultures that remained consistently positive throughout treatment.

All the delinquent cases were negative for more than a month and were probably cured, but since further observation was impossible, they have been deleted from Table 4.

In cases considered probable reinfections, the patients either had spermatozoa in the smears or admitted sexual contact. The recurrence of positive findings was due either to reinfection or to exacerbation of a latent infection. We believe that most of these cases must have been reinfections, but since it cannot be proved, we have deleted the cases from Table 4 rather than class them as cured cases that had been reinfected, or as definite fail-

res It is our impression, however, that in series of well controlled and checked, such cases might be considered drug failures

that received sulfanilamide, 14 per cent that received sulfapyridine, 7 per cent that received sulfathiazole, and 4 per cent that received sulfadiazine were drug failures. The outcome of these failures is given in Table 5.

In this group of 453 women, there were 44 pregnant patients, of whom 6 were reinfected but were cured on subsequent treatment; 8 with repeated reinfections were deleted from the series. Three pregnant patients were discharged cured by sulfanilamide, 8 by sulfapyridine, 20 by sulfathiazole

41 (24 per cent) children were drug failures; 5 had failed to respond to previous sulfonamide therapy. One drug fast strain was produced. All the children in whom drug-fast strains were produced were treated and cured with stilbestrol or a combination of stilbestrol and sulfonamide therapy *

Blood Concentration

Blood concentrations as high as 10 mg. per 100 cc. were obtained in patients who received sulfanilamide, but most of them were between 3 and 4 mg. per 100 cc. With sulfapyridine and sulfathiazole, the highest levels were 8 mg. per 100 cc., most of them being between 2 and 3 mg. With a 2 gm. daily dose of sulfadiazine, the concentration in the blood was usually between 4 and 6 mg. per 100 cc. Earlier, when a 3 gm. daily dose was used, levels between 8 and 11 mg. per 100 cc. were frequent. These seemed unnecessarily high and might be dangerous in ambulatory patients. For that reason, the daily dose of sulfadiazine was lowered to 2 gm. There was no increase in the number of failures with this lower dose.

Toxicity

A large number of patients who received sulfanilamide and sulfapyridine exhibited minor toxic symptoms. The number of toxic symptoms with

zole, and 4 by sulfadiazine. There were drug failures in 5 cases: 2 with sulfanilamide, 1 with sulfapyridine and 2 with consecutive courses of sulfanilamide, sulfapyridine and sulfathiazole. The latter 2 patients recovered after delivery when given sulfathiazole. Of the 2 patients who did not respond to sulfanilamide, one became delinquent and the other was cured with sulfapyridine. The patient in whom sulfapyridine failed to effect a cure was subsequently cured with sulfathiazole.

In gonococcal vulvovaginitis, 13 of 15 (89 per cent) children who received sulfanilamide were drug failures, and 5 drug fast strains were produced. With sulfapyridine, 12 of 49 (25 per cent) children were failures—5 of these had previously been failures with sulfanilamide. Two drug-fast strains were produced. With sulfathiazole, 10 of

sulfadiazine was about as great as that with sulfathiazole, but both drugs were better tolerated than sulfanilamide or sulfapyridine. Very rarely was it necessary to discontinue treatment because of toxic symptoms.

DISCUSSION

It has been shown that diagnosis and cure of gonococcal infection must be based on cultures rather than smears.⁶ In a study of 216 patients with one thousand six hundred and seventy five cultures, over 50 per cent of the positive cultures had corresponding negative smears. Moreover, many patients showed persistently positive cultures, although the smears were consistently negative. Conversely, only 0.5 per cent of the positive smears had corresponding negative cultures.

*The dose of stilbestrol was as follows: 0.1 mg. three times a day for thirteen to twenty days.

infected during the two-month observation period that followed therapy. We believe that these patients suffered two or more infections and have, therefore, designated *each infection* as a *case*, regardless of whether the patients received previous therapy. Accordingly, one patient might constitute two or more cases, making a total of 604 cases in all. Of these, 155 received sulfanilamide, 222 sulfapyridine, 166 sulfathiazole and 61 sulfadiazine.

DISCUSSION

It has been shown that diagnosis and cure of gonococcal infection must be based on cultures rather than smears.⁵ In a study of 216 patients with one thousand six hundred and seventy five cultures, over 50 per cent of the positive cultures had corresponding negative smears. Moreover, many patients showed persistently positive cultures, although the smears were consistently negative. Conversely, only 0.5 per cent of the positive smears had corresponding negative cultures.

*The dose of stilbestrol was as follows: 0.1 mg. three times a day for thirteen to twenty days.

The reliability of initial diagnosis or of cure, whether on the basis of smear or culture, is largely dependent on the technic used in the collection of material. Good smears are unquestionably more difficult to obtain in women than in men, but with care they can be prepared quite easily. The material must be taken from sites that harbor the gonococcus, such as Skene's, Bartholin's and the endocervical glands. Material from the vagina or the vaginal introitus rarely contains gonococci after subsidence of the acute stage of the infection. Moreover, material from this area is usually so badly contaminated with vaginal bacteria that the slides are unreadable and the cultures are overgrown.

The meatus of the urethra should be wiped dry with a piece of cotton to avoid inclusion of confusing vulval bacteria. The finger should then be passed within the vagina, and the urethra firmly stripped from above downward against the pubic arch. A cotton swab may be used for collection of the material.

To obtain satisfactory specimens from the cervical glands, the cervix should be exposed with a speculum inserted without lubrication other than water. The vaginal secretion should be wiped out, and the plug of cervical mucus mechanically removed. The cervix should then be compressed with the speculum, to force the secretion from the endocervical glands, and the material removed on a cotton swab inserted directly into the cervical canal. Some workers prefer to insert the swab and then compress the cervix with the speculum.

The great discrepancy between positive cultures and smears has led us to try various methods for collection of the material. With smears prepared from swabs as compared with those prepared with a platinum loop, we obtained more positive slides with swabs than with loops, although the pus cells in smears made with the loop were less distorted than those made with swabs.

A comparison of the results of cultures taken during and just following the menstrual period indicates that occasionally a positive culture is obtained during the menstrual period and not postmenstrually, but the number is hardly large enough to warrant the procedure, since most patients object to visits during the period. Postmenstrual smears and cultures, however, are quite essential. Frequently, positive results are obtained at this time and at no other time.

A comparison of the results of cultures taken following the menstrual period with the results obtained after a provocative test with silver nitrate has convinced us that the menstrual period is the best provocative test of cure of gonococcal infection

in women. Cultures taken the first day after the provocative test, as is the usual custom, may lead to erroneous conclusions. We have had a small series of patients who had positive cultures on the postmenstrual day, the day on which the provocative test was done. Although positive cultures were again obtained on the fourth postprovocative day, the cultures taken on the first postprovocative day were negative. Therefore, if a provocative test is done, cultures taken on the third or fourth day after the test rather than the first day are better criteria of cure. These data will be published later.

Previously, we had required that patients be observed through three negative menstrual periods and provocative tests before they could be discharged as cured, but in 235 patients, only 2 patients who gave no evidence of reinfection became positive during the third month of observation. Both became delinquent, and further information to substantiate the evidence of drug failure could not be obtained. It seems, therefore, that observation through two menstrual periods is sufficient.

The results with sulfonamide therapy in women lead to the conclusion that sulfathiazole (93 per cent cure) and sulfadiazine (96 per cent cure) are the drugs of choice for the treatment of gonorrhea in women. Sulfapyridine gives quite good results (86 per cent cure), but patients complain of minor toxic symptoms more frequently than they do with sulfathiazole or sulfadiazine. An occasional case that has been a failure with sulfathiazole responds to sulfapyridine. Sulfanilamide is definitely better than local treatment, but it is the poorest (76 per cent cure) of the sulfonamide compounds studied. Moreover, it requires larger doses for a longer time than the other compounds do. Response to treatment is more rapid with sulfathiazole and sulfadiazine than with sulfanilamide. With sulfanilamide, 88 per cent of the patients who were cured had negative cultures within four days after treatment was begun. With sulfapyridine, 93 per cent; with sulfathiazole, 97 per cent; and with the small series of sulfadiazine patients, 98 per cent of the cultures were negative within four days. Women, therefore, respond rapidly to sulfonamide therapy. In a previous series of patients who received local therapy (2 per cent Mercurochrome), there were only 80 per cent failures after six weeks of treatment.⁴

Only relatively small doses of the sulfonamides are necessary for cure. We believe that the high percentage of cures in our series has been dependent somewhat on the low dosage of drugs given. Patients are better able to tolerate small

amounts of the drug. They are more willing to take the drug and are better able to retain it than when large doses are given.

With the sulfonamides, secondary complications are relatively rare if therapy is begun early.

Drug fast strains are not readily produced in women. In our series of 453 patients, only 1 patient gave evidence of so-called "drug-fastness," and she became delinquent, so that definite proof was lacking. Not infrequently, we have had patients who were supposed failures with all the drugs, but careful check has always shown that this was due to reinfection and not to drug fastness of the particular strain of the gonococcus.

Our series of pregnant patients is too small to permit definite conclusions. The 12 per cent failure rate is somewhat higher than that in the nonpregnant group. It is possible that, as in certain other infections, gonorrhea may be more resistant to treatment during pregnancy. Two of the 5 patients who were drug failures in this group failed to respond to treatment until the post partum period. All the patients were checked post partum. None of the infants developed the infection, and none of them seemed to have been adversely affected by the treatment during pregnancy.

Gonorrhea in children is more difficult to diagnose and to control than in adults. Cultures are not quite so reliable as in adults, and smears are much more liable to error, primarily because other cocci present in the vagina may be confusing. It is essential that smears be carefully stained (by Gram's method) and controlled to avoid over-decolorization.

Children require larger doses of sulfonamides for a longer time than adults do. Previous studies indicated that a ten day course of treatment is the minimum in children, and at least 0.75 gm per 20 pounds of body weight should be the minimum dose with sulfapyridine and sulfathiazole. So far, too few patients have received sulfadiazine for us to know whether or not the dose may be lowered.

Sulfanilamide is definitely contraindicated in the treatment of children because it tends to produce drug fast strains, hence so few cases in this series. Sulfapyridine and sulfathiazole are about equally effective, but sulfathiazole produced fewer minor toxic symptoms. The occasional drug-fast strain has responded to treatment with stilbestrol or a combination of stilbestrol and sulfonamide therapy, but since we have discontinued

the use of sulfanilamide we have encountered only three such strains.

We have had considerable difficulty in determining whether or not some of the children had become reinfectors or were failures. In no case in which we were certain that the recurrence was due to a failure has that recurrence taken place after the third month following therapy. Three months, therefore, is probably long enough to check children before they are discharged as cured.

SUMMARY AND CONCLUSIONS

Sulfonamides were used in the treatment of gonococcal infection in 453 women and 80 children.

Diagnosis and cure should be based on cultures as well as smears.

Patients should be observed through two negative menstrual periods before they are discharged as cured.

Sulfathiazole and sulfadiazine are the drugs of choice for the treatment of women. The rate of cure with sulfanilamide was 76 per cent, with sulfapyridine 86 per cent, with sulfathiazole 93 per cent and with sulfadiazine 96 per cent.

Women respond rapidly to sulfonamide therapy and become noncontagious much earlier than when local treatment is used. Of those cured with sulfathiazole, 97 per cent had negative smears and cultures within four days after treatment was begun; with sulfadiazine, 98 per cent responded within four days.

Secondary complications are rare if sulfonamides are administered early. None of the patients discharged as cured required surgical treatment for complications.

Drug fast strains of gonococci are produced extremely rarely in women: 1 in 453 patients.

Sulfathiazole is the drug of choice in the treatment of vulvovaginitis in children. Sulfanilamide is contraindicated.

- 5 Hac L R, Hesselstine H C, Adair F L and Hils D K. Preliminary report on transportation of materials for gonococcal cultures. *Am J Obst & Gynec* 41:98-105 1941.

The reliability of initial diagnosis or of cure, whether on the basis of smear or culture, is largely dependent on the technic used in the collection of material. Good smears are unquestionably more difficult to obtain in women than in men, but with care they can be prepared quite easily. The material must be taken from sites that harbor the gonococcus, such as Skene's, Bartholin's and the endocervical glands. Material from the vagina or the vaginal introitus rarely contains gonococci after subsidence of the acute stage of the infection. Moreover, material from this area is usually so badly contaminated with vaginal bacteria that the slides are unreadable and the cultures are overgrown.

The meatus of the urethra should be wiped dry with a piece of cotton to avoid inclusion of confusing vulval bacteria. The finger should then be passed within the vagina, and the urethra firmly stripped from above downward against the pubic arch. A cotton swab may be used for collection of the material.

To obtain satisfactory specimens from the cervical glands, the cervix should be exposed with a speculum inserted without lubrication other than water. The vaginal secretion should be wiped out, and the plug of cervical mucus mechanically removed. The cervix should then be compressed with the speculum, to force the secretion from the endocervical glands, and the material removed on a cotton swab inserted directly into the cervical canal. Some workers prefer to insert the swab and then compress the cervix with the speculum.

The great discrepancy between positive cultures and smears has led us to try various methods for collection of the material. With smears prepared from swabs as compared with those prepared with a platinum loop, we obtained more positive slides with swabs than with loops, although the pus cells in smears made with the loop were less distorted than those made with swabs.

A comparison of the results of cultures taken during and just following the menstrual period indicates that occasionally a positive culture is obtained during the menstrual period and not postmenstrually, but the number is hardly large enough to warrant the procedure, since most patients object to visits during the period. Postmenstrual smears and cultures, however, are quite essential. Frequently, positive results are obtained at this time and at no other time.

A comparison of the results of cultures taken following the menstrual period with the results obtained after a provocative test with silver nitrate has convinced us that the menstrual period is the best provocative test of cure of gonococcal infection

in women. Cultures taken the first day after the provocative test, as is the usual custom, may lead to erroneous conclusions. We have had a small series of patients who had positive cultures on the postmenstrual day, the day on which the provocative test was done. Although positive cultures were again obtained on the fourth postprovocative day, the cultures taken on the first postprovocative day were negative. Therefore, if a provocative test is done, cultures taken on the third or fourth day after the test rather than the first day are better criteria of cure. These data will be published later.

Previously, we had required that patients be observed through three negative menstrual periods and provocative tests before they could be discharged as cured, but in 235 patients, only 2 patients who gave no evidence of reinfection became positive during the third month of observation. Both became delinquent, and further information to substantiate the evidence of drug failure could not be obtained. It seems, therefore, that observation through two menstrual periods is sufficient.

The results with sulfonamide therapy in women lead to the conclusion that sulfathiazole (93 per cent cure) and sulfadiazine (96 per cent cure) are the drugs of choice for the treatment of gonorrhea in women. Sulfapyridine gives quite good results (86 per cent cure), but patients complain of minor toxic symptoms more frequently than they do with sulfathiazole or sulfadiazine. An occasional case that has been a failure with sulfathiazole responds to sulfapyridine. Sulfanilamide is definitely better than local treatment, but it is the poorest (76 per cent cure) of the sulfonamide compounds studied. Moreover, it requires larger doses for a longer time than the other compounds do. Response to treatment is more rapid with sulfathiazole and sulfadiazine than with sulfanilamide. With sulfanilamide, 88 per cent of the patients who were cured had negative cultures within four days after treatment was begun. With sulfapyridine, 93 per cent; with sulfathiazole, 97 per cent; and with the small series of sulfadiazine patients, 98 per cent of the cultures were negative within four days. Women, therefore, respond rapidly to sulfonamide therapy. In a previous series of patients who received local therapy (2 per cent Mercurochrome), there were only 80 per cent failures after six weeks of treatment.⁴

Only relatively small doses of the sulfonamides are necessary for cure. We believe that the high percentage of cures in our series has been dependent somewhat on the low dosage of drugs given. Patients are better able to tolerate small

infection without stones. Two patients had the so-called "postcholecystectomy syndrome." All the 11 patients with common duct involvement had jaundice; the remaining 7 were not jaundiced. Eight patients gave a history of colic shortly before admission.

Nine patients had electrocardiographic abnormalities on admission to the hospital. In 6 out of 7 of these patients, the carotid sinus reflex was found to be insensitive when re-examined postoperatively or after the jaundice had subsided. This observation makes pre-existent myocardial disease—that is, disease of the effector organ—unlikely as the major factor in the production of the reaction. Whether there were other functional factors affecting the myocardium cannot be stated. Unfortunately, it is not known whether the electrocardiographic abnormalities also disappeared, but other observers have noted a return of the electrocardiogram toward normal in similar patients after operation.⁹ The electrocardiographic changes included sinus bradycardia, prolonged PR interval, notching and slurring of the QRS complexes, RT depressions and T-wave inversions. In 2 cases, the bradycardia was striking, a rate of 40 to 45 per minute being a prominent feature. Both patients were jaundiced. In 1 case, changes suggestive of an anterior-wall myocardial infarction developed after abdominal pain and icterus had subsided; the clinical course and x-ray findings suggested that common duct obstruction, which was apparently spontaneously relieved, was followed by myocardial infarction, presumably due to acute coronary occlusion. Two patients showed auricular fibrillation, which was paroxysmal in 1 and coincided with an episode of acute biliary colic. Six of the patients who showed electrocardiographic changes also presented evidence of varying degrees of arteriosclerosis involving the major vessels.

The carotid sinus reflex was re-examined postoperatively or after the acute symptoms had subsided in 10 of the 18 patients. In 6, the hypersensitive reflex disappeared promptly. In 1 patient with carcinoma of the head of the pancreas, both jaundice and a positive reflex persisted after cholecystgastrostomy, suggesting that the obstruction had not been completely relieved. One patient with the postcholecystectomy syndrome lost the reaction for several days when olive oil was introduced into the duodenum.

Atropine sulfate effectively blocked the cardio-inhibitory reflex in all cases in which it was tested. The subcutaneous injection of 1 mg was usually sufficient. Tincture of belladonna by mouth was also effective, but less regularly.

Seven patients had spontaneous symptoms, consisting of dizziness, faintness, sudden weakness, syncope or collapse. In 4, these symptoms occurred during acute episodes of colic; the other 3 suffered recurrent symptoms in association with ill-defined gastrointestinal complaints.

The following cases are illustrative.

CASE 1 S T, a 51-year-old man, entered the hospital because of jaundice and upper abdominal discomfort. The patient related that several weeks before admission he experienced a sudden episode of upper abdominal discomfort during which he fainted. On the following day, he noted dark urine and a light stool, and thereafter discovered that he had become jaundiced. Tarry stools were not noted.

The patient had had mild hypertension (a blood pressure of 160/100) and auricular fibrillation for several years.

Massage of the carotid sinus resulted in prolonged asystole.

Operation revealed a carcinoma of the ampulla of Vater, partially obstructing the common bile duct. Further observation could not be carried out because the patient died shortly after an attempt at resection.

CASE 2 S S, a 45-year-old man, had a cholecystectomy performed 3½ years before admission because of recurrent episodes of epigastric pain, nausea, vomiting, icterus and acholic stools. The gall bladder was found to be thickened and to contain stones, and the common duct contained chilly material. A year after operation, the patient began to have frequent bouts of pressing epigastric pain radiating up under the sternum, associated with nausea, dizziness, lachrymation, sweating, faintness and, occasionally, actual syncope. The attacks lasted about 15 minutes, and were promptly relieved by belching. Jaundice and acholic stools had not been noted.

Physical examination revealed no pertinent findings. There was no icterus. X-ray examination of the abdomen and the electrocardiogram revealed no abnormalities.

Massage of the right carotid sinus caused asystole of 5 or 6 seconds, faintness, nausea, eructation, lachrymation and, finally, syncope. The symptoms produced were identical with those occurring spontaneously, except for the absence of abdominal pain. Olive oil introduced into the duodenum by tube under fluoroscopic control resulted in a flow of bile and a loss of the carotid sinus reaction for 2 days. This was repeated on two occasions. One milligram of atropine sulfate injected subcutaneously completely abolished the carotid sinus reflex reaction. On a high fat diet and tincture of belladonna by mouth, the patient noted a distinct decrease in spontaneous symptoms and the carotid sinus reflex was found to be much less sensitive.

CASE 3 D B, a 43-year-old man, was admitted to the hospital because of fainting spells occurring after meals. These were associated with upper abdominal distention, eructation and nausea, and particularly followed the ingestion of fatty foods. Jaundice or acholic stools had not occurred.

Carotid sinus massage yielded prolonged asystole, which was followed by syncope when the patient was examined in the erect position. The patient was hypersensitive to pain by the Libman test.

At operation, a thickened gall bladder containing numerous faceted stones was removed. One week after operation, it was no longer possible to elicit any carotid sinus reaction.

In Case 1, the abdominal discomfort and syncope, followed promptly by the classic signs of common-duct obstruction, suggest the possibility of sudden reflex cardiac standstill, in association with the development of the obstruction. The demonstration of a hypersensitive, cardioinhibitory carotid-sinus reflex favors the view that the vagal-reflex arc was overactive.

Cases 2 and 3 illustrate recurrent syncopal symptoms as the dominant feature of the clinical picture. The nature of the so-called "post-cholecystectomy syndrome" remains uncertain, but it is not unusual to find a greatly dilated common duct on exploration. In Case 1, there was no evidence of a persistent stone, and the absence of jaundice ruled out effective obstruction. The common duct was not involved in Case 2. It is significant that in both the therapy most effective in relieving the symptoms referable to the biliary-tract disorder also relieved the syncopal symptoms and carotid-sinus-reflex sensitivity to a similar degree.

Analysis of negative cases. Five of the 23 patients with biliary-tract disease showed no response on carotid-sinus massage. All had infection and stones in the gall bladder, and in no case was the common duct found to be involved at operation. One patient was jaundiced and may have passed a stone, but this could not be established at operation. The ages of the patients ranged from thirty-three to fifty-eight years. Two patients had biliary colic. None of the patients had any spontaneous symptoms related to syncope. Two patients had electrocardiographic changes.

Toxic Hepatitis

Thirteen proved cases of toxic hepatitis were studied, to evaluate the role of jaundice in this reaction. The patients' ages ranged from nineteen to sixty-eight years, 9 being over forty-one (Table 1). All patients were jaundiced at the time of examination. Only 1 showed a positive response to carotid-sinus massage. This was a thirty-three-year-old woman with chronic alcoholism, acute alcoholic cirrhosis, beriberi heart disease and peripheral neuritis. The carotid-sinus reaction disappeared before the jaundice had subsided. The occurrence of the cardioinhibitory type of reflex during nutritional deficiency and chronic alcoholism has been commented on by others.¹⁰ No patients had any spontaneous symptoms related to syncope. Two patients showed advanced peripheral arteriosclerosis and hypertension. Two patients had electrocardiographic changes indicating myocardial damage.

Control Cases

To obtain some idea of the incidence among the average ward population of positive reactions satisfying the criteria already described, 81 patients, of whom 55 were over forty years of age, were examined at random (Table 2). In this group,

TABLE 2. Age Incidence in Control Cases.

AGES	NO. OF POSITIVE CASES	NO. OF NEGATIVE CASES
yr.		
12-20	2	3
21-30	0	11
31-40	2	8
41-50	4	17
51-60	5	17
61-70	1	8
71-80	2	1
Totals	16	65

16 patients, or 19 per cent, yielded a positive reaction. Among the 55 patients over forty years of age, positive reactions occurred in 12 cases, an incidence of 22 per cent. This incidence is identical with that observed by Sigler,¹¹ who found asystole of three seconds or more to occur in 18 per cent of 1886 patients between ten and eighty-five years of age and in 23 per cent of 1332 patients between forty and eighty-five years.

The diagnoses in the positive cases included acute rheumatic carditis, 5 cases; coronary-artery disease, 4 cases; arteriosclerosis, 2 cases; cancer of the viscera, involving peritoneum and diaphragm, 3 cases; and Graves's disease and duodenal ulcer, 1 case each.

The negative cases included the usual conditions encountered in a general hospital medical service, and were in no fashion a selected group except for the omission of several patients in whom the presence or absence of biliary-tract disease could not be established with certainty.

DISCUSSION

The pathologic factors leading to sensitization of the carotid-sinus-reflex arc are many. The production of cardiac asystole may depend on involvement of the reflex arc anywhere along its course, including the afferent and efferent pathways as well as the central synapses.¹⁰ Local disease of or around the carotid sinus, such as arteriosclerosis and neoplastic or inflammatory masses in the neck, presumably involves the afferent nerve endings or pathways. Coronary-artery and myocardial disease, particularly when the conduction system is involved as in acute rheumatic carditis, affects the efferent end of the cardioinhibitory reflex arc. Vascular or degenerative disease of the central nervous system may involve the central synapses. Other

factors, such as dietary insufficiency, menstruation and digitalis, have been noted, but the exact sites of action have not been explained.¹⁰

In the cases under consideration, it is noteworthy that the reaction occurred most frequently among the patients with common-bile-duct involvement. Increase in bile pigments in the blood is not the determining factor, as is clearly indicated by the negative results among the patients with icterus of nonobstructive origin. Whether other substances that accumulate in obstructive jaundice, particularly the bile acids and their derivatives, are concerned in this reaction is more difficult to say. Balticeano and Vasilu^{12, 13} report that when sodium taurocholate or sodium glycocholate (0.25 to 0.5 gm.) is injected into the common carotid artery or around the carotid sinus of dogs, bradycardia and hypotension result. This reaction does not occur after denervation of the carotid sinus, after vagal section or when the material is injected distal to the carotid sinus. The positive reactions among the nonicteric patients, with subsequent recovery on subsidence of the acute episodes or after operative intervention, indicate that retention of bile salts is only one of the contributory factors and that further experimental observation is necessary to clarify this point. In the 2 patients with postcholecystectomy syndrome, both of whom had positive carotid-sinus reactions as well as spontaneous syncopal symptoms in association with gastrointestinal complaints and neither of whom had jaundice, it might be presumed that only the biliary passages were involved. It may be recalled that in 1 of these cases the introduction of olive oil into the duodenum by tube, a procedure that initiated a generous flow of bile, was followed by inability to elicit the carotid-sinus reaction for several days. When the patients without involvement of the common duct and without icterus are considered, the incidence of positive reactions is less than 50 per cent.

The evidence presented thus suggests that this phenomenon represents a summation reaction. The production of cardiac standstill in icteric animals by manipulation of the bile passages has already been commented on. In all likelihood, the asystole produced by massage of the carotid sinus does not represent an increased sensitivity of the carotid sinus itself, but results from a summation of impulses reaching the medullary centers. If impulses were to arise constantly from the distended or diseased bile passages, the addition of afferent impulses from the carotid sinus as well might then exceed the threshold of reaction of the vagal centers, with consequent cardiac inhibition. Whether there are additional factors actively influencing the heart itself is as yet unknown. The possibilities

of such indirect sensitization of a previously hypotensive cardioinhibitory reflex arc are now being investigated, and positive results have already been obtained in a number of cases. Thus, in 1 patient, the inflation of a balloon in the duodenum resulted in a complete sinus arrest, followed by an idioventricular rhythm (a rate of 45 per minute) that persisted until the tube was removed ten minutes later. For some time thereafter, although normal sinus rhythm had been restored, the slightest pressure on the carotid sinus led to a prolonged cardiac standstill. This, and similar cases, will be the subject of a more detailed report at a later date. Thus, the spontaneous reactions of bradycardia and cardiac standstill depend on a number of variable factors, any one or combination of which may be sufficient to exceed the threshold of reaction and produce symptoms. It is doubtful, however, whether the spontaneous symptoms of syncope in the cases with biliary-tract disease arise from mechanical involvement of the carotid sinus itself, except in unusual cases. It is more reasonable to suppose that the symptoms originate reflexly from impulses arising in the efferent end organs located in relation to the biliary tract. Massage of the carotid sinus simply provides a convenient means of establishing the presence of such an overactive reflex arc.

From these data, it becomes quite apparent that the finding of a hyperactive carotid-sinus reflex is evidence only of the existence of a sensitized nervous pathway, whose cause may be located anywhere along the carotid-sinus-reflex arc itself or along any one of a number of related pathways. Failure to recognize this point has led to an unfortunate overemphasis on the diagnostic and therapeutic significance of the carotid sinus itself, frequently with indifferent results. Equally misleading have been the recent attempts to attribute a greater value to the hyperactive cardioinhibitory carotid-sinus reflex than to the electrocardiogram as a diagnostic aid in coronary disease.^{11, 11} Without attempting to minimize the role of coronary disease as a sensitizing factor, one must point out that its diagnostic value is decidedly limited unless corroborative clinical or laboratory evidence is present. The greatest value of demonstrating a hyperactive carotid-sinus reflex is the attention that it directs toward certain critical points of the reflex arc that may become sensitized. Other clinical and laboratory observation may then serve to identify the underlying pathologic process responsible for this sensitization.

Comment might be made on the relation of these reflex symptoms to pain sensitivity. It is an interesting clinical observation that patients with a hypersensitive carotid-sinus reflex rarely com-

plain of pain on massage of the neck, even in the prone position, when unconsciousness usually does not occur. Libman¹⁵ has called attention to the fact that, in patients who are hyposensitive to pain, symptoms referable to the autonomic nervous system sometimes dominate the clinical picture. In 2 of the patients described in an earlier section, spontaneous symptoms of faintness, sweating, weakness and syncope clearly overshadowed the gastrointestinal symptoms. Both patients were hyposensitive to pain by the Libman test of styloid pressure. One might speculate on the possibility that the sympathetic reflexes induced by severe pain might ordinarily tend to counteract the vagal cardioinhibitory reflex, but that in the absence of the former, the vagal reflexes dominate, resulting more readily in syncope and related symptoms.

SUMMARY

The cardioinhibitory carotid-sinus reflex was examined in 23 patients with more or less acute symptoms due to biliary-tract disease, 13 patients with toxic hepatitis, and 81 ward patients selected at random.

Eighteen, or 78 per cent, of the patients with biliary-tract disease had asystole of three seconds or more on massage of the carotid sinus. Of these, 11 had common-duct obstruction and jaundice, 5 had cholecystitis and cholelithiasis, and 2 had the postcholecystectomy syndrome. In 10 patients, the carotid-sinus reflex was re-examined after the acute symptoms had subsided and was found to be negative in 6. Seven patients had spontaneous symptoms consisting of dizziness, faintness or syncope in association with symptoms referable to the biliary tract.

The 5 patients who failed to yield positive reactions had cholecystitis and cholelithiasis, without involvement of the ducts.

Among the 13 patients with toxic hepatitis, only 1 showed an overactive cardioinhibitory reflex.

Among the 81 ward patients examined at random, only 16, or 19 per cent, yielded positive reactions. The diagnoses in the positive cases included acute rheumatic carditis, coronary-artery disease, arteriosclerosis, cancer of the viscera, hyperthyroidism and duodenal ulcer.

The reaction is considered to be the result of a summation of afferent impulses and not a sensitization of the carotid sinus itself. The major portion of these impulses probably arises from afferent end organs in the region of the biliary tract, but when further impulses from the carotid sinus are added to the reflex arc, the threshold of reaction of the vagal centers is reached and cardiac inhibition ensues. The clinical significance of the hyperactive carotid-sinus reflex is discussed from the point of view of the various sites at which the reflex arc may become sensitized by disease.

QUININE METHOCHLORIDE TREATMENT OF SPASTIC CHILDREN*

Preliminary Report

EDWARD PRESS, M.D.[†]

EAST PROVIDENCE, RHODE ISLAND

CURARE, a drug paralyzing voluntary musculature,¹ has been used successfully to reduce muscle spasm in patients with cerebral palsy,¹ and thereby to accelerate their treatment program. However, curare is of rather indeterminate composition, is still difficult to obtain, and is effective only when given by repeated parenteral injection. Quinine methochloride, a recently synthesized drug readily available in pure form, is said to have a curare-like action when given by mouth.^{2,3} Since it is thus free from the obvious disadvantages of curare, the present study was undertaken to determine whether it is equally effective in the treatment of cerebral palsy.

MATERIAL AND METHODS

Quinine methochloride, a white powder of low density and intensely bitter taste, is poorly soluble in water. Since some children with cerebral palsy have difficulty swallowing capsules, it was necessary to devise another method of administration. The drug dissolves only slightly in alcoholic and watery solutions, and syrups and elixirs could therefore not be used. A satisfactory method was finally devised whereby the desired amount was well dispersed in cherry syrup of thick consistence. The medicine glass was then rinsed with plain or flavored water, which the patient drank. Thus, the entire dose was given in a manner similar to that in common usage with the sulfonamide drugs in children.

The drug[‡] was administered orally in gradually increasing doses to the 6 children with cerebral palsy previously treated with curare by Denhoff and Bradley¹ with a reasonable degree of success. An accurate comparison of the two drugs in individual patients was thus facilitated. The same general method of determining the optimum dose as that used by Denhoff and Bradley with curare was employed. Only one dose a day was given at first, to avoid any possible cumulative effect. An initial dose of 25 mg per kilogram of body weight was given, and this was increased by successive increments of 5 mg per

kilogram until unfavorable effects occurred. Following this, it was discontinued for several days and then resumed in a lower dosage three times daily for six days. Two of the latter periods were used for therapeutic evaluation—the first in which each dose was half the toxic dose and the second, directly following, in which two thirds the toxic dose was used.

The children studied ranged in age from eight to twelve years. Three presented varying degrees of spasticity alone, 1 had a combination of spastic and athetotic elements, and 2 showed athetotic movements with no spastic components. All were resident patients at the Emma Pendleton Bradley Home during the entire period covered by the observations. Except for the time spent in the performance of specific tests, each child continued his usual daily activities of physiotherapy, academic schooling, occupational therapy and free play throughout the period of study.

CRITERIA FOR EVALUATION

The children were continuously under the daily supervision of the same physiotherapist and trained nurses of the permanent hospital staff, who kept detailed records of the children's activities and reactions. In addition, during the entire experiment, as well as several days preceding and following this period, daily observations and examinations were made. These examinations included the extent of flexion and extension of spastic limbs; the mode and changes in walking and writing; the degree of fullness and length of time that a glass of water could be held; use of pin board, peg ball and tracing board, and more general subjective and objective observations. As a control measure, these same examinations were carried out with the patients receiving curare, curare placebos and no medication.

The electrical threshold for obtaining muscular contractions at four motor points on each patient was also used in an attempt to determine the extent and presence of the curarizing effect. It was realized that this method included the stimulation of some of the muscle fibers directly in addition to the motor itself. However, the more exact method described by Harvey and his associates⁷ was not considered practicable on these children at the time

*From the Emma Pendleton Bradley Home, East Providence, Rhode Island. Formerly, resident physician, Emma Pendleton Bradley Home.
[†]Quinine methochloride was supplied through the courtesy of E. R. Squibb and Sons, New York City.

Analyses of venous blood to determine the effectiveness of absorption from the gastrointestinal tract and the concentration of quinine methochloride in the blood were done. A modification of the method described by Prudhomme¹⁰ was used. Determinations of the blood pressure, pulse and respiratory rate, as well as complete blood counts and urinalyses, were repeated at frequent intervals before, during and after administration of the drug.

RESULTS

In an effort to obtain definite beneficial effects the dose was gradually increased until undesirable results were elicited in each patient. The dose necessary to cause these varied, in different patients, from 125 to 140 mg. per kilogram of body weight. This amounted to single doses of from 2.5 gm. (37 gr.) to 4.9 gm. (73 gr.), and was less than the 150 to 200 mg. of quinine methochloride per kilogram that Harvey⁶ found to be necessary for oral curarization in cats. Following doses of 80 to 90 mg. per kilogram, blood levels in these patients varied from 4.7 to 23.4 mg. per 100 cc. and averaged 13.8 mg.

On several of the tests and examinations used to evaluate the effects of the drug, an increased relaxation and muscular co-ordination often associated with a decrease in athetotic movements was apparent. However, this was no greater than the frequent variations in the condition of the same children at times when they were receiving curare placebos or no medication. No appreciable change in the electrical stimuli necessary to cause contractions at the motor points was noted.

The unfavorable manifestations in order of frequency were as follows: malaise and a feeling of lethargy and inertia; nausea and vomiting; diarrhea (with repeated daily doses only); and

ringing in the ears. It is interesting that only 1 patient complained of ringing in the ears. This occurred only once, and subsequently when the dose was slowly increased this symptom did not recur. No abnormalities were detected in repeated blood counts, urinalyses or determinations of blood pressure and respiratory rate.

No constant therapeutic effect was noted with quinine methochloride on the 6 children under observation. This was in contrast to the favorable influence of a preparation of curare on the same children.

SUMMARY

Quinine methochloride given orally to 6 children with cerebral palsy in doses that were increased until undesirable results were obtained failed to give a demonstrable curarizing effect. There was no definite evidence that this drug had a beneficial influence on any of the children.

A RARE TYPE OF ACUTE THROMBOCYTOPENIC PURPURA: WIDESPREAD FORMATION OF PLATELET THROMBI IN CAPILLARIES*

MARK D ALTSCHULE, M D †

BOSTON

IT has long been known that thrombocytopenic purpura is a syndrome occurring in a variety of diseases, such as leukemia and other myeloid phthisic states, aplastic anemia and severe infections, and in reactions to a number of chemical substances. There remains a large group of cases of thrombocytopenia in which careful study reveals no etiologic factor, these are usually called "essential thrombocytopenic purpura." It is probable that this group is not homogeneous. Treatment in patients with acute essential thrombocytopenic purpura is frequently not curative, but spontaneous remissions are common, temporary control of the hemorrhagic manifestations usually follows transfusion, and more lasting relief may occur as a consequence of splenectomy. Accordingly, most physicians exhibit optimism regarding the outcome of the initial attack of purpura in these patients. A patient with essential thrombocytopenic purpura recently died in this clinic, however, the course being rapidly progressive, uninflected by transfusion and otherwise clinically different from that seen in most cases of this disease.

Study of the literature revealed 5 previously reported cases that resembled this one, in all, death occurred after a short illness. In 1936, Baehr, Klemperer and Schiffrin¹ reviewed the data in 4 unusual cases of thrombocytopenic purpura, including one studied by Friedberg and Gross² and another by Gitlow and Goldmark.³ Baehr and his co-workers defined the clinical characteristics and pathological findings common to all these patients and pointed out their resemblance to those of the incompletely studied case reported previously by Moschcowitz.⁴

The present case is reported to call attention to this rare type of essential thrombocytopenic purpura. The clinical manifestations of this syndrome are distinctive, and the correct diagnosis may be made ante mortem in the future.

CASE REPORT

A 50 year old Russian born woman (B.H. 58758) entered the hospital complaining of general malaise and abdominal pain of 4 days duration. There was a family history of diabetes, hypertension and rheumatic fever, one

child had died of tuberculosis. The patient had had scarlet fever, measles and pertussis as a child, and for many years had had chronic pelvic inflammatory disease that was treated by means of two operations. The first operation, 6 years before admission, resulted in menopausal symptoms. The second, a hysterectomy, was performed 18 months before admission, at that time, hypertension was noted, but no evidence of anemia. The patient had some what more bleeding during the operation than is usually seen, but transfusion was not considered necessary. She had been careful of her diet for years, but it was within normal limits qualitatively and quantitatively except for some deficiency in fruit juices. The patient was well until approximately 3 weeks before admission, when she began to notice easy fatigability. Four days before admission, generalized aches and pains developed, particularly over the back and about the joints of the extremities. Severe headaches, dizziness and attacks of diffuse abdominal pain associated with vomiting also occurred on that day. The patient vomited approximately a dozen times, the vomitus containing small amounts of bright red blood. On the next day, cough, productive of a small amount of whitish mucoid material streaked with blood, developed, and a severe nosebleed occurred. Spontaneous bowel movements were absent during the 4 days preceding entry to the hospital, but enemas resulted in satisfactory evacuations. On the 3rd and 4th days of the acute illness, arthralgia, headache and malaise persisted, but otherwise the patient felt improved. She was sent to the hospital on the 4th day of her acute illness by Dr. Morris Rutenberg.

Examination was negative except for pallor, petechiae over the legs and face, slight smoothness of the edges of the tongue, old healed abdominal scars, tenderness throughout the abdomen, enlargement of the liver (5 cm below the costal margin), and a spleen that was palpable at the costal margin. The blood pressure was 115/70. Ophthalmoscopic examination was negative.

Sixteen specimens of urine contained small amounts of albumin and a variable number of erythrocytes and leukocytes. The specific gravities ranged between 1.002 and 1.012. Bence Jones protein was not present in the urine. The red-cell count on admission was 1,800,000 with a hemoglobin of 38 per cent (Sahli), and the white-cell count was 13,400 with 80 per cent polymorphonuclear cells, 15 per cent lymphocytes, 4 per cent monocytes and 1 per cent eosinophils. The platelet count was 54,000, the reticulocyte count 2.2 per cent, the bleeding time over 30 minutes, and the clotting time 2 minutes. The clot retracted poorly. Examination of the stool was negative. The blood nonprotein nitrogen level was 33 mg and the cholesterol level 313 mg per 100 cc, with 142 mg per 100 cc, esters, the blood uric acid level was 5.6 mg, and the serum protein level was 6.1 gm per 100 cc, and the icteric index was 10. Gastric analysis revealed no free hydrochloric acid in the fasting specimen and only small amounts in subsequent specimens. The blood Hinton and Kahn reactions were negative. Bone marrow biopsy revealed normal bone marrow. Lumbar puncture on the 7th day revealed normal findings.

*From the Medical Service, Beth Israel Hospital and the Department of Medicine, Harvard Medical School.

†Associate in Medicine, Harvard Medical School, associate visiting physician, Beth Israel Hospital.

The patient was given a high-vitamin, high-protein diet, with fluids ad libitum, 100 mg. cevitamic acid by mouth daily, and vitamin B complex and cod-liver oil concentrates by mouth. The rectal temperature ranged between 98.6 and 101.0°F. during the first 5 days and then rose progressively to 107°F. on the 9th day, with corresponding changes in the pulse rate. The respiratory rate was not elevated until the 8th day, when it rose to 40 per minute.

Autopsy (1 hour post mortem). The gross findings consisted in generalized pallor, icterus, ecchymoses in the skin of all the extremities, numerous petechiae in the pericardium, endocardium, myocardium, mucosa of the stomach, duodenum, ileum and rectum, and large areas of hemorrhage in the pleuras, bladder wall and both adrenal medullas. The spleen and liver were enlarged, weighing respectively 540 and 2000 gm. The other gross findings

FIGURE 1. *Stages in the Resorption of Platelet Thrombi.*

A—*fresh thrombi*; B—*growth of endothelium over the thrombi*; C—*resorption of the thrombus, with thickening of the capillary wall.*

The patient received 500 cc. of citrated blood on the 3rd, 5th and 8th days after admission, and 1000 cc. of blood on the 7th day, as well as intravenous infusions of physiologic saline and glucose solutions from time to time. The red-cell count never rose above 2,800,000, remaining most of the time between 1,600,000 and 1,900,000, with corresponding hemoglobin levels. The white-cell count varied between 10,000 and 21,000, with a decrease in polymorphonuclear leukocytes, beginning on the 7th day, to between 52 and 58 per cent. The bleeding time was usually more than 30 minutes, decreasing to 11 minutes on only one occasion; the clotting time was always less than 2 minutes. The platelet count decreased progressively to 11,000, and the reticulocytes varied between 7.0 and 12 per cent. Many suppled and small numbers of nucleated erythrocytes were seen. On the 3rd day, the patient became confused, exhibiting mumbling speech and left facial weakness; these signs disappeared completely after a few minutes. Fresh purpuric spots appeared on the face and extremities on that day, and from time to time thereafter. On the 5th day, severe headache developed, and the next day the patient became restless and disoriented as the temperature rose. The icteric index increased to 18. Roentgenograms of the chest revealed findings suggestive of pneumonia, and sulfathiazole was started. The patient rapidly failed, becoming increasingly delirious and somewhat more icteric. She vomited several hundred cubic centimeters of coffee-grounds material, containing clots, on the day of her death.

included congestion of the spleen and of the bronchial and gastric mucosa, edema of the kidneys, slight atheromatous changes in the aorta and several old fibrous bands adherent to the old healed abdominal scars.

Microscopic examination confirmed the gross findings and revealed, in addition, numerous capillary thrombi in the pancreas and heart, a moderate number in the adrenal glands, kidneys and gastrointestinal tract, and a few in the spleen and liver. The thrombi in a few glomerular capillaries also involved the afferent arterioles. Elsewhere, arterioles, venules and larger vessels appeared normal. The capillary thrombi varied from a few platelets adherent to the endothelium to masses of platelets, either recently deposited or else, becoming amorphous and finally shrunken, rather hyaline masses. The capillary endothelium showed evidence of proliferation in these areas, growing over the surface of the masses of platelets; it sometimes remained thickened after resorption of most of the thrombus. There was a minimal leukocytic or fibroblastic reaction in a few areas.

Microscopic examination also revealed acute bronchitis, with early bronchopneumonia, an increase in the number of lymphocytes in the periportal areas in the liver and slight hyalinization of the media of the splenic arterioles.

DISCUSSION

The clinical manifestations in the case reported resemble closely those of the syndrome discussed

by Baehr et al.¹ The disorder, which has been noted only in females, is characterized by rapidly progressive anemia, mild icterus, purpura hemorrhagica and fever. Melena, hematemesis and hematuria may occur; the terminal manifestations consist in stupor, delirium, restlessness and other evidences of intracranial disease. Respiratory infections may precede the appearance of purpura. In addition to anemia, the blood shows leukocytosis, reticulocytosis, the presence in the circulating blood terminally of immature red blood cells, and profound thrombocytopenia. The bleeding time is prolonged, and the tourniquet test is positive; the clotting time is normal, although the clot reacts poorly. Transfusion has no apparent beneficial effect, and death occurs within two weeks to two months after the onset. Splenectomy was performed in 1 of the previously reported cases,¹ and was followed by the death of the patient.

At autopsy, the significant findings consist in normal bone marrow, hemorrhages into the viscera and a large number of thrombotic lesions within the capillaries and, to a lesser extent, the arterioles. Studies made by means of differential stains show these thrombi to consist of masses of platelets, erythrocytes and fibrin are not found in the thrombi. The adjacent endothelium is seen to be proliferating, growing into or over the surface of the thrombi. In some areas, the thrombi are completely covered with endothelium and appear to be shrunken, dense and homogeneous, as if undergoing resorption. It appears that thrombosis occurs in various parts of the body in a succession of attacks. In spite of widespread occurrence of thromboses, there is little or no evidence of parenchymal necrosis.

The rapidly progressive course of the disease, the failure to respond to transfusion, the uniform occurrence of icterus and cerebral manifestations and the specific pathological findings of widespread platelet thrombi are characteristic of this type of thrombocytopenic purpura. Attempts to relate this syndrome to acute disseminated lupus erythematosus because of the purpura and the finding of vascular lesions³ are not valid. The disorder exemplified by the patient in the case reported

above is not characterized by the lymphadenopathy, edema, effusions, signs of pleural and pericardial involvement, specific rash, leukopenia and endocarditis commonly encountered in acute disseminated lupus. Moreover, the vascular lesion is different, consisting in primary alterations in the walls of the blood vessels in lupus, as contrasted to platelet thrombosis in the syndrome of the present discussion.

Baehr et al.¹ suggested that the profound thrombocytopenia seen in this syndrome might be due to withdrawal of enormous numbers of platelets from the circulation, they discussed the possibility that this phenomenon, in a less easily detected form, might occur in other cases of thrombocytopenic purpura. The cause of the damage to the vascular endothelium, which results in deposition of platelets as seen in the syndrome of the present report, is unknown; Schwartzman, Klemperer and Gerber² pointed out the similarity of the vascular lesion in this syndrome to the changes in the blood vessels of animals in which the Schwartzman phenomenon has been induced.

SUMMARY

A case of a rare type of essential thrombocytopenic purpura characterized by the formation of numerous platelet thrombi in the capillaries throughout the body is described.

The syndrome is differentiated from other varieties of essential thrombocytopenic purpura by rapid progression, failure to respond to transfusion and splenectomy and the uniform occurrence of icterus and cerebral manifestations.

MEDICAL PROGRESS

SURGICAL CARE AND OPERATIVE TECHNIC

JOHN D. STEWART, M.D.*

BUFFALO, NEW YORK

NATURALLY enough, the current surgical literature is concerned to a considerable extent with the problems of military medicine, but nevertheless there are contributors who find time for the persistent challenge present in such subjects as hernia, appendicitis and gastrointestinal distention. Evidence is presented favoring the wider applicability of surgical treatment, and one is reminded that it is the physiologic rather than the chronologic age of the patient that matters.¹ As an increasing proportion of the population succeeds in reaching elderly ages, the surgeon is given a chance to show that cancer of the rectum or cancer of the stomach, as examples, can be successfully operated on despite the patient's years.² Furthermore, operative methods are being developed for palliative or curative treatment of hitherto hopeless lesions, such as carcinoma of the esophagus and carcinoma of the pancreas.

WOUND HEALING

What are considered the fundamental principles of the treatment of traumatic wounds are tabulated and discussed by Reid and Carter.³ Hemostasis, débridement, immobilization, avoidance of chemical irritants, preservation of blood supply and maintenance of proper nutrition are among the indisputable points mentioned. Sterilization of fresh traumatic wounds can be only relative, and reliance must be placed on the power of healthy living cells to combat bacteria. Tetanus and gas-bacillus antitoxins are used prophylactically whenever the nature of the wound and the severity of its soiling so indicate. From an experimental study of fresh traumatic and contaminated surgical wounds, Bisgard and Baker⁴ conclude that bactericidal agents applied to wounds do not prevent infection but may cause severe tissue damage and interference with repair. Sulfanilamide, on the other hand, is locally protective and nonirritating. Copious irrigation of the wound with physiologic saline solution is standard practice, but these authors seem to favor mechanical scrubbing of the wound itself while it is being irrigated. In my opinion, such trauma is to be avoided.

The surgeon who prefers to use catgut routinely can find sound instruction based on the physiology of wound healing in an article by Howes.⁵ The complications of wound healing are reduced in number by a decrease in the size of the catgut used, and according to the author no catgut larger than No. 0 need be employed in suturing fascia. Catgut should be used sparingly or not at all in tissues that tolerate catgut poorly, such as the skin, subcutaneous fat, mucous membranes and muscles, but it is overwhelmingly the suture of choice in contaminated wounds. Plain catgut is to be used where rapid healing is to be expected, as in serosal and mucosal surfaces, and in the ligation of all vessels except large arteries, which are not safely sealed off until fibrosis has occurred.

In a rather fantastic communication,⁶ a method is proposed for avoiding exogenous operative contamination completely, based on complete sterilization of the operating room with its contained air and equipment by means of formaldehyde gas. The operating room is hermetically sealed and is entered through four sterile anterooms. Surgeons and patients discard all clothing before entering the sterile rooms and are dressed in sterile overall gowns, which cover the entire body like diving suits. "The patient's skin is cleansed with benzene and then treated for at least ten minutes with a freshly prepared 10 per cent iodine solution, which it is generally unnecessary to remove by means of alcohol." The paper is provocative, and although the methods proposed seem cumbersome to the point of inapplicability, one must admit that it is all too easy to compromise with practical requirements in the matter of surgical asepsis.

Further evidence of the value of vitamin C in wound healing appears in the recent literature as obtained in both clinical and animal research. Patients undergoing operation on the biliary tract in the presence of depleted vitamin C reserves, as shown by the study of the dietary history or determinations of plasma concentrations, are reported to develop a higher incidence of incisional hernia than patients without such depletion.⁷ However, the same authors concluded that, in 12 cases of abdominal-wound disruption, mechanical factors were more frequently to be blamed than vitamin C deficiency. Bartlett, Jones and Ryan^{8,9} report

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress: Annual, Vol. III, 1942* (Springfield, Illinois: Charles C. Thomas Company, 1942. \$5.00).

*Professor of surgery, University of Buffalo School of Medicine, surgeon-in-chief, Edward J. Meyer Memorial Hospital.

further data from their painstaking investigations in animals and in patients, and Hartzell and Stone¹⁰ submit evidence of similar significance. The latter workers found histologically a failure of collagen production in experimental wounds when vitamin C deficiency was present. Greater than normal tensile strength did not result from an increase in the vitamin C intake above the normal daily requirement, which emphasizes the general conclusion that no benefit is to be expected from an excess of vitamins.

The possible value of vitamin A in wound healing has come under study, but the data do not appear to be decisive. Brandaleone and Popper¹¹ found that wounds made in the abdominal wall of vitamin A deficient rats were epithelialized more rapidly if cod liver oil was applied locally or given orally. Cod liver oil produced no results if vitamin A depletion did not exist. Cod liver oil contains, of course, various substances, some known and some unknown, and the authors offered as control observations the finding that linseed oil applied to the wounds of vitamin A deficient rats did not affect the rate of wound healing.

PROTEIN DEFICIENCY IN SURGICAL PATIENTS

The problem of maintaining nitrogen balance and restoring deficits before and after operation continues to engage the attention that the great importance of the problem deserves. Amino acid mixtures obtained by hydrolytic breakdown of beef, milk and wheat have been used in tube feeding, with satisfactory clinical results.¹² A casein hydrolysate (Amigen), which apparently contains all the essential amino acids, has been given intravenously in several hundred patients with only an occasional mild urticarial reaction.¹³ The authors are convinced that this is the simplest and most convenient way of supplying large amounts of utilizable nitrogen parenterally, and my own experience with infusions of casein hydrolysate leads me to agree. In my studies, the solution has been given at somewhat faster rates without reaction, and with only moderate and transitory elevation of amino acid concentration in the patient's blood. The excretion of amino acids in the urine during and after such infusions appears to be trivial.¹⁴

Brunschwig, Clark and Corbin¹ studied nitrogen balance in a group of 41 patients undergoing a variety of major surgical operations. During the ten days immediately following operation, a nitrogen deficit varying from 38 to 175.8 gm was observed in 36 patients. The major factor in the nitrogen loss appeared to be restriction of food intake, although the trauma to tissues at operation and acceleration of metabolism probably contributed. The postoperative nitrogen deficit could be

reduced or even prevented by intravenous infusions of casein hydrolysate. The authors conclude that casein digest and glucose may be employed to maintain and replete nitrogen stores—a conclusion that others have reached before them.

ACUTE APPENDICITIS

Of the various papers on this subject appearing in the past year, several are notable. The exhaustive clinical study of Faxon and Rogers^{15, 17} deserves the attention of the surgeon or internist interested in the acute abdomen. In the clinical appraisal of cases of appendiceal peritonitis, the presence or absence of a mass seemed an advantageous criterion. Of the 671 cases of acute appendiceal peritonitis, in 444 a mass was not present, and the postoperative mortality rate was 15.9 per cent, in the 227 cases with a mass, the rate was 7.1 per cent. The authors state that incision and drainage alone should be done as a primary procedure unless technical removal of the appendix can be readily accomplished, and this principle is especially vital after the fourth day of the disease. Appendectomy should be carried out within six weeks following incision and drainage, as a rule. In the cases without a palpable mass in the right lower quadrant, the highest operative mortality resulted from operation on the fourth or fifth day of the disease. These patients were treated before the use of sulfonamide drugs was introduced in the care of peritoneal infection, and therefore this factor did not enter the study. One of the findings in the survey illustrates the treacherous nature of clinical statistics. The observation was made that appendectomy lasting between fifty and sixty minutes results in about half the mortality rate of either longer or shorter operations. From this, the unimaginative surgeon might conclude that if he found himself getting through the operation before fifty minutes he should find some way of prolonging the procedure to the point of safety.

Guerry and McCutchen¹⁸ discuss the operative handling of the localized appendiceal abscess, as based on extensive personal experience. Mobilization of the head of the cecum, protection of adjacent areas from soiling, proper placing of the omentum and stab wound drainage are among the details recommended. In the illustrations of operative technic, too much gauze seems to be packed into the wound, but the artist may have given a wrong impression.

INGUINAL HERNIORRHAPHY

A number of recent papers on this subject are at hand. In some, the anatomic details are clearly illustrated, a welcome matter to medical students, who realize the shortcomings of the standard text.

books of anatomy in this respect. McVay and Anson¹⁹ discuss what they consider a fundamental error in current methods of inguinal herniorrhaphy, namely, suturing the inguinal layers to Poupart's ligament. They state, "The superior pubic ligament (Cooper's ligament) should be used instead, for it is the normal insertion, it is readily accessible and it is intrinsically strong and directly fixed to bone." After the sac is removed or imbricated as the case may be, the superior pubic ligament is isolated and freed of adjacent preperitoneal connective tissue. The inferior margin of the transversus abdominis aponeurosis and attached transversalis fascia is clarified and sutured to the superior pubic ligament from the pubic tubercle to the femoral vein.

An entirely different approach to the problem is proposed by Jennings, Anson and Wright.²⁰ A low midline suprapubic incision is made down to the peritoneum, and the peritoneum is stripped away from the rectus muscle on the involved side to expose the internal abdominal ring. The hernial sac is either withdrawn or transected at the ring, and the peritoneum proper is usually not entered. Among the advantages of the method are listed avoidance of trauma to the inguinal planes, simplicity of technic, less chance of injuring the ilioinguinal nerve and spermatic cord, and less danger of infection. The authors recognize the limitations of the method, however, and state that it is not applicable to direct or large indirect inguinal hernias, and that major anesthesia and abdominal relaxation are required. The paper is unusually well illustrated.

Clinical and experimental evidence on the use of the buried cutis graft in the repair of hernia is briefly reviewed by Cannaday,²¹ who reports personal experience with the technic. Skin is regarded as better for plastic repair than fascia, on the grounds that skin is "more active," has longer life and is stronger and more resistant to pressure or strain. The author states that cutis may be used in superimposed layers in reconstructing the planes of the abdominal wall. In the experimental studies cited, it was found that the sebaceous glands and hair follicles in the implanted derma disappear early, the sweat glands later. Cannaday apparently has not noted wound infection, such as might come from the bacteria present in the glands and follicles of the buried skin.

CARCINOMA OF HEAD OF PANCREAS

This difficult surgical problem is receiving much study, and definite progress can be reported. Harvey and Oughterson²² have performed local excision of an ampullary growth in 1 case and radical pancreaticoduodenectomy in 5, with 1 fatality.

These authors believe that pessimism is unwarranted and that earlier diagnosis and radical excision of such growths are indicated. Their clinical experience suggests that the external secretions of the pancreas in some patients do not appear to be essential to life. Whipple²³ discusses the reasons for the reluctance hitherto shown by surgeons in tackling carcinoma of the pancreas, and in speaking of technical details points out the great superiority of fine silk over catgut in pancreatic surgery. For carcinoma limited to the papilla of Vater, transduodenal resection, with reimplantation of the common and pancreatic ducts into the duodenum, offers definite advantages in his opinion. Sallick and Garlock²⁴ take a gloomy view and favor routine management of noncalculous obstructive jaundice by external biliary drainage as the initial operative procedure. If the patient survives for more than six months, the lesion is assumed to be benign, and a secondary operation is planned. They state that biliary-intestinal anastomosis at the outset in their series of cases resulted in an operative mortality rate of 48 per cent. Such an attitude appears unjustifiable in view of the palliative results and possible cures being obtained at present in various clinics by bold surgical operation. Attentive preoperative and postoperative care and skill and experience in biliary-tract surgery are undoubtedly requisite in the successful handling of carcinoma of the pancreas.

Fatty infiltration and degeneration of the liver occur not infrequently in carcinoma of the pancreas and the papilla of Vater, and protective preoperative and postoperative measures are analyzed by Schnedorf and Orr.²⁵ The feeding of lecithin, choline, pancreatic extract or lipocaic is recommended as part of the routine management, since the presence of a high concentration of lipid in the liver is associated with impairment of liver function. The authors have hopes that thorough investigation of pancreatic function in patients with vague abdominal complaints may lead to earlier diagnosis of growths in the head of the pancreas or the papilla of Vater. Trimble, Parsons and Sherman²⁶ report another successful one-stage operation for carcinoma of the head of the pancreas. Their patient showed no evidence of interference with the digestion of fat, carbohydrate and protein eleven months after pancreaticoduodenal resection.

A great contribution to the surgical treatment of lesions of the head of the pancreas consists in the report of Ziegler.²⁷ In studying the blood supply of the head of the pancreas in 24 cadavers, he found the gastroduodenal artery to be remarkably constant in its origin, course and distribution, but in 2 cases it gave origin to the middle colic artery. When the gastroduodenal artery does not give

rise to the middle colic artery, preliminary ligation of the gastroduodenal artery and the pancreaticoduodenal artery can be used to render excision of the head of the pancreas and duodenum a relatively bloodless dissection.

SPLENECTOMY

Two suggestions concerning the technic of splenectomy in difficult cases are worthy of mention. When the convex surface of the spleen is densely adherent to the parietal peritoneum, Rives⁸ advises stripping away the parietal peritoneum along with the spleen instead of trying to separate the adhesions. Singleton²⁹ exposes the splenic artery along the upper border of the pancreas by sectioning the gastocolic ligament. After ligation of the artery, the hilum of the spleen is dealt with in the usual manner, with much less danger of uncontrollable bleeding.

Hamrick and Bush³⁰ report a case of splenosis of the peritoneum and review a part of the literature on the subject. In their case, splenectomy was performed for traumatic rupture of the spleen, and the patient remained well for three and a half years. After death from other causes, autopsy revealed numerous nodules of splenic tissue, up to 4 cm. in diameter, scattered throughout the peritoneal cavity. Microscopically, the tissue was similar to the structure of the adult spleen, with capsule, follicles (without germinal centers) and red pulp containing sinuses filled with red blood cells. This interesting condition is apparently seen only in young persons in whom seeding of the peritoneum with splenic cells has occurred following trauma. No subcutaneous implants have been reported, and no cases have been reported following splenectomy for nontraumatic lesions.

GASEOUS DISTENTION OF GASTROINTESTINAL TRACT

Altmeier and Wadsworth³¹ describe intestinal ileus as a complication of fractured rib and report 10 cases. Irritation of the dorsal sympathetic ganglions and splanchnic nerves appears to be the most plausible explanation, as produced by displacement of the fractured bone, by retropleural edema or hematoma in the paravertebral area or by reflex stimulation of the splanchnic nerves through the peripheral abdominal or thoracic nerves. In 8 of the 10 cases, the fracture was within 5 cm. of the lateral vertebral border. The condition is best treated conservatively without operation if ruptured intra-abdominal viscus can be ruled out.

The free use of nasogastric suction during and after operation is advocated by Singleton, Rogers and Houston.³² The advantages of maintaining

deflation of the gastrointestinal tract through aspiration of swallowed air are summarized, as well as some possible disadvantages of the method. Careful restoration of water and electrolyte lost in this manner is necessary to avoid dehydration and acid base imbalance. Analyses of intestinal gases from dogs with intestinal obstruction are in agreement with the findings of earlier students of the subject, notably McIver, and indicate that most of the gas is swallowed air, since 84 per cent is nitrogen.

Studies of the effects of various drugs on the motility of the human colon are reported by Adler, Atkinson and Ivy.³³ Prostigmine methylsulfate, pituitary extract and ergotamine tartrate were tested with respect to their effect on propulsive motility in the distal colon of 4 patients with colostomies. A combination of the drugs seemed to give better results with less side reaction than a larger dose of the drugs used singly.

DICUMAROL

Experimental and clinical study of the usefulness of 3,3'-methylenebis(4-hydroxy coumarin), or dicumarol, continues.³⁴ This substance causes hemorrhagic sweet clover disease in cattle, and has been isolated, identified and synthesized by Link and his co-workers.³⁵ When 100 to 300 mg is taken orally by the adult patient, retardation of clotting and prolongation of prothrombin time promptly ensue, so far, toxic side actions do not appear to occur. The clotting defect persists for several days, and the only known method of shortening the recovery period is blood transfusion. It seems probable that the drug has clinical applicability in the treatment and prevention of intravascular clotting, thrombophlebitis and pulmonary embolism, as well as in arterial surgery and in sulfonamide therapy of established infection. Preliminary reports suggest that patients may safely be operated on after the clotting mechanism has been inhibited by the drug, although further data are needed.³⁶ In the clinical use of dicumarol, it will probably be necessary to take careful note of individual variation in dosage requirements by frequent measurements of clotting time or prothrombin time, a disadvantage that the method shares with the inhibition of clotting by heparin. The pharmacologic action of the drug remains to be determined, but liver damage is apparently not the basis for its effect.

TRACY B. MALLORY, M.D., *Editor*

CASE 28391

PRESENTATION OF CASE

A fifteen-year-old schoolgirl was admitted to the hospital because of severe crampy abdominal pain and jaundice.

Seven weeks prior to admission, the patient had a "head cold." This cleared after a week, and she went to the seashore, where she developed a "remarkable tan." Several days later, the scleras were found to be jaundiced.

Five weeks before admission, generalized jaundice developed, unassociated with symptoms other than listlessness and anorexia, and became progressively deeper. A physician treated the patient with a diet limited to fluids. Ten days before entry, she suffered with distention and an attack of severe crampy midabdominal pain, which lasted several hours and was relieved by the passage of flatus and a "diarrhea" stool. Since this episode, attacks of similar pain had become increasingly severe and occurred more frequently. The passage of flatus and loose stools — often ten to twelve times a day — always provided some relief. The attacks bore no relation to meals and frequently awakened the patient from sleep. The stools varied from green to clay but prior to admission seemed to have been most often clay colored. The stools were not tarry and did not contain blood. The urine gradually developed a wine color. A week before entry, when examined at this hospital, the patient was deeply jaundiced. Examination of the heart and lungs was negative. The spleen was felt three fingerbreadths below the costal margin. The temperature was 98°F., and the pulse 100. The patient was advised to remain in bed, take her temperature twice a day, and consume a high-carbohydrate, low-fat diet. Three days later, the patient developed skin ecchymosis on the anterior chest and buttocks. She stated that at this time the attacks of abdominal pain culminated, with some relief in vomiting of copious amounts of fluid. She denied any contact with unusual chemicals or drugs, and there was no evident exposure to rats. During the illness, she gained approximately 17 pounds.

The family history was irrelevant. Four years before entry, an appendectomy was performed be-

cause of "acute appendicitis." Two years later, an abscess of the left kidney was drained, and recovery was complete after two weeks. Catamenia had not appeared for nine weeks.

Physical examination revealed a listless, deeply jaundiced and dehydrated girl who complained bitterly of intermittent attacks of crampy epigastric pain in the left side and across the upper abdomen. The attacks lasted one or two minutes, with a few minutes' interval of relief, and were suggestive of labor pains. Examination of the heart and lungs was not remarkable except for a short systolic murmur audible in the pulmonic area. The abdomen was markedly distended and tympanitic. No masses could be felt because of the degree of distention. There was moderate tenderness over the upper abdomen and to the left of the umbilicus. Dullness was percussed in the right upper quadrant from the fifth rib to three or four fingerbreadths below the costal margin. Peristaltic sounds were diminished in intensity and frequency. There was a slight degree of bilateral ankle edema.

The blood pressure was 140 systolic, 70 diastolic. The temperature was 103.2°F., the pulse 120, and the respirations 30.

Examination of the blood revealed a red-cell count of 4,100,000 with a hemoglobin of 10.5 gm., and a white-cell count of 13,000 with 93 per cent polymorphonuclear neutrophils. The hematocrit was 47 per cent. The urine was the color of port wine and acid in reaction, had a specific gravity of 1.012, showed a + + + + test for bile, and contained 5 to 10 white blood cells and 3 to 5 granular casts per high-power field. The stool was semisolid and tan.

The guaiac test was markedly positive, and bile pigment was found to be present. The nonprotein nitrogen was 12 mg. per 100 cc., and the van den Bergh reaction 37.6 mg., direct. The prothrombin time was 75 seconds (normal, 22 seconds). The phosphorus was 2.3 mg. per 100 cc., and the phosphatase 3.3 Bodansky units. A flat plate of the abdomen showed a diffuse haziness. There was no evidence of dilated loops of bowel. In one film, there was a large amount of gas in the stomach.

In spite of supportive treatment in the form of the administration of vitamin B complex, vitamin K, glucose and citrated blood, the patient lapsed into coma and died two days after admission.

DIFFERENTIAL DIAGNOSIS

DR. ALLAN M. BUTLER: Let us briefly enumerate some of the salient features of this history. Seven weeks prior to admission, the patient had

a head cold. Ten days later, she developed jaundice. During the next three and a half weeks of jaundice, there was no fever, pain, vomiting or diarrhea. Five and a half weeks after the onset of jaundice, she suffered from distention, abdominal pain and diarrhea. For a considerable period of the jaundice, there was bile in the stools. The wine-colored urine leads me to assume that there was a mixture of bilirubin, urobilinogen and urobilin in the urine.

When first examined at this hospital six weeks following the onset, the patient was still deeply jaundiced and still had no fever. There was also no bradycardia. The advice to remain in bed and consume a high-carbohydrate, low-fat diet makes one wonder whether the examining physician made the diagnosis of catarrhal jaundice.

DR. TRACY B. MALLORY: The first visit to the hospital was to the Out Patient Department. At that time, the patient was given a house appointment and entered the ward a week later.

DR. BUTLER: I assume that the skin ecchymoses reflected the hypoprothrombinemia of jaundice, which is to be distinguished from vitamin K deficiency. With the former, there is plenty of vitamin K getting in, but in the presence of liver damage it is not convertible to prothrombin.

The absence of fever, I should think, is against Weil's disease. In asking about unusual chemicals or drugs, the physicians were searching for the etiologic factor of the toxic hepatitis.

The distention of the abdomen was, I presume, largely due to ascitic fluid.

One wonders if a hepatitis was not mistaken for appendicitis, or whether with the appendicitis something occurred that caused injury to the liver. We know that colon bacillus infections of the kidney may result in colon bacillus septicemia and consequent hepatitis.

I assume that the pain in the left side and across the upper abdomen had to do with splenic congestion, possibly pancreatitis, gastric dilatation or adhesions about the duodenum. At this point, no mention is made of ascites, but I assume that ascites was present. Apparently, the liver was enlarged, but the edge was not made out, so that we do not know whether it was a smooth edge. No mention is made of any prominent superficial abdominal veins. The serum protein concentration is not reported.

A week after the visit to the Out Patient Department, the temperature rose to 103.2°F. The hemoglobin and cell counts indicate that the patient was not having a hemolytic crisis. The urine contained bile, white cells and granular casts. No mention is made of urobilin or epithelial cells. Bile was present in the stool. The low blood

nonprotein nitrogen probably reflects the high-carbohydrate, low-protein diet and the low blood urea from liver damage. The serum alkaline phosphatase was not elevated as I should have anticipated with this degree of jaundice and liver disease. No blood Hinton or tuberculin reaction is reported.

The facts that x-ray examination showed no evidence of dilated loops of bowel and that the patient was continually having stools indicate no intestinal obstruction.

Do the x-ray films deserve demonstration, and does an x-ray man want to interpret them or do I have to?

DR. MALLORY: I am sorry, but no x-ray man is here.

DR. BUTLER: The films suggest ascites, with diffuse haziness throughout the abdominal cavity, an elevated diaphragm and some congestion at the bases. The heart is pushed up by the elevation of the diaphragm that results from the abdominal distention, which in turn is due to ascites.

If I had been asked to see the patient at this point in her course, I think I should not have said that she had syphilis, actinomycosis, an echinococcal cyst or other parasitic infection or a liver abscess. There was no history of trauma to initiate liver damage. The chances are very much against cholelithiasis, and I do not believe the primary disturbance was related to a cholangitis or that the patient had a portal cirrhosis. Therefore, I conclude that she probably had a toxic hepatitis.

As a pediatrician who does not see a great deal of liver disease in patients of this age, I should have called in a consultant.

I had hoped to be able to call in Dr. C. M. Jones, but unfortunately he is on vacation, so that I cannot benefit by his opinion. From the subsequent course of the patient, it appears that she did not obtain such benefit either.

The best I can do without that consultation is to say that this patient died in cholemia from liver insufficiency due to toxic hepatitis. Since the physical examination suggested an enlarged liver, the pathological diagnosis might well be hypertrophic biliary cirrhosis following a toxic hepatitis, with simultaneous degeneration and regeneration of the liver cells. Or it may be that the degeneration was acute enough to warrant the diagnosis of subacute yellow atrophy.

The etiology, I should think, would remain unknown. We have seen several patients with such a course of disease, and the etiology has been unknown. Strangely enough, Dr. L. K. Diamond at the Children's Hospital has seen three children of one family with a story like this, and the diagnosis was the one that I am making in this case.

I believe that Dr. Jones encountered another family in which several children with similar stories were thought to be suffering from toxic biliary cirrhosis.

I think it will be found that the splenomegaly was of the obstructive type. There may have been some pancreatitis. If there was a portal or splenic thrombosis, it was secondary and did not play a great part in the present course, because portal or splenic thrombosis usually leads to death from repeated esophageal and gastric hemorrhages after a considerable period. If such thrombosis were primary, we ought to have more comment about superficial abdominal veins, collateral circulation and, possibly, esophageal varices. There may have been extrahepatic obstruction of the common duct due to tumor or enlargement of the lymph nodes of the portal fissure. Although nothing was said about epithelial cells in the description of the urine sediment, I should think the kidneys would show cloudy swelling of the tubular epithelium with desquamation of some of the epithelial cells. Because of the past history of draining of a perinephritic abscess, some healed pyelonephritis should be evident at autopsy.

A PHYSICIAN: Is there a possibility of subacute bacterial endocarditis? Were there any blood cultures?

DR. MALLORY: There were no blood cultures. I think this degree of jaundice would be very unusual for bacterial endocarditis.

A PHYSICIAN: Was there a history of pregnancy?

DR. MALLORY: No.

DR. WILLIAM W. BECKMAN: I was bothered by the fact that the spleen was enlarged at the time of the first examination, and I wondered if there were an underlying process, such as splenic thrombosis or cirrhosis.

CLINICAL DIAGNOSIS

Acute yellow atrophy of liver, etiology?

DR. BUTLER'S DIAGNOSIS

Toxic hepatitis.

ANATOMICAL DIAGNOSES

Subacute yellow atrophy of liver

Ascites

Icterus

Peritonitis, chronic fibrous, localized, postoperative.

Operative scar, appendectomy.

Hydrothorax, slight, right.

PATHOLOGICAL DISCUSSION

DR. MALLORY: Dr. Butler has not been present at these exercises very long and, consequently,

does not know the pleasure I take in presenting cases with palpable livers that turn out to be extremely small and atrophic. Of all points in physical examination I think the estimation of the size of the liver is the most unreliable, and totally so in any patient with ascites.

This patient had a liver weighing 1050 gm., which represents a moderate degree of atrophy. It was coarsely nodular, the nodules ranging up to a little more than 1 cm. in size. They were interspersed with deep and rather large depressions in which liver cells are absent. The picture corresponds very closely to what we interpret here as the healed stage of acute atrophy.

One wonders how long the process had been developing. The history was only a little over six weeks in duration, whereas the liver shows considerable fibrosis, rather more than I should suppose could be accounted for merely by condensation of the stroma. The scars are still quite vascular, however, and there are still numerous mononuclear phagocytes, which presumably were attracted by disintegrating liver cells. All active degeneration of liver cells has ceased, and regeneration is still active.

There had also been time for well-marked hypertrophy of the spleen, which weighed 650 gm. The sinusoids are dilated, and the splenic pulp is fibrotic, as one sees in any case with portal hypertension. There were not any readily demonstrable evidences of collateral circulation, however, but esophageal varices are difficult to demonstrate at autopsy even when seen clearly at fluoroscopic examinations during life. I have recently heard of an apparently well-authenticated similar case in which death from a ruptured varix occurred six weeks after the onset of epidemic infectious hepatitis. If this is correct, cirrhosis and portal hypertension must, on occasions, develop with much greater rapidity than we have hitherto supposed. The kidneys, as predicted, show a moderate degree of tubular degeneration consistent with so called "bilonephrosis." There were no other significant findings.

The etiology, as predicted, remains completely mysterious. My inclination is to consider it due to infectious hepatitis,—that is, catarrhal jaundice,—but in the absence of an epidemic I know of no way to prove the point.

A PHYSICIAN: I should like to ask about the nonprotein nitrogen of 12 mg. per 100 cc. That is not a normal figure.

DR. BUTLER: The patient had been living on a low-protein, high carbohydrate diet and had liver disease.

CASE 28392

PRESENTATION OF CASE

A forty-three-year-old man was admitted because of crampy abdominal pain.

Two and a half years before admission, the patient suffered with a gastrointestinal upset, which lasted one day and was characterized by diarrhea, but had no vomiting. Eight months later, he had several attacks of abdominal pain and vomiting, each lasting several weeks. Following each attack, he was quite well. One and a half years before entry, he consulted a physician because of an attack of epigastric distress, which developed after he ate bacon. This attack was characterized by recurrent periods of periumbilical colicky pain, each lasting several hours and somewhat relieved by belching and vomiting. During the attacks, diarrhea developed. However, the stools remained normal in color and did not contain blood or mucus. The physician told the patient that he had a tendency toward ulcer and treated him successfully with a bland diet. Ten days before admission, after a similar attack, he entered a community hospital, where a gastrointestinal barium study was said to have been negative. On the night before admission to this hospital, the gastrointestinal distress recurred and was similar to previous episodes, except that the pain was severer. Obstipation had developed, but no vomiting occurred. During the three months prior to entry, the patient had lost 20 pounds in weight.

The family and past histories were irrelevant.

Physical examination revealed a well-developed, very restless, haggard man who was obviously acutely ill. The skin was dry, and the tongue dry and coated. Examination of the lungs was negative. There were soft apical and basal systolic murmurs. The abdomen was distended, and in the left epigastrium, there was a smooth, nontender mass, which descended with respirations. No edge and no irregularity of the mass could be distinguished. In the left lower quadrant, there was a firm, smooth, movable, baseball-sized mass, which was tender and dull to percussion. There was no abdominal-wall spasm, and no rebound tenderness. Peristalsis was diminished.

The blood pressure was 122 systolic, 88 diastolic, and the temperature was 100°F., the pulse 96, and the respirations 24.

The blood revealed a hemoglobin of 14.900. The urine had a specific gravity of 1.020, gave a ++ test for diacetic acid and a + test for sugar, and contained many cells per high-power field (a

saline-glucose infusion was administered prior to the collection of this urine specimen). The blood Hinton reaction was negative. A flat plate of the abdomen revealed numerous loops of dilated bowel, particularly of the small bowel. There was some gas in the dilated cecum. The stomach was displaced upward by the dilated loops of bowel. There was a large soft-tissue mass in the left side of the abdomen.

Gastrointestinal decompression was initiated by means of a Miller-Abbott tube. A barium enema was then performed. The barium flowed to the cecum without delay. There seemed to be pressure on the sigmoid by a soft-tissue mass. There was no definite evidence of obstruction in the colon. A large amount of fecal material was present. Numerous loops of dilated small bowel were visible.

Operation was performed on the second day after admission.

DIFFERENTIAL DIAGNOSIS

DR. HORACE K. SOWLES: In this patient with a history of somewhat less than two years of real trouble, the attacks suggest to me mechanical interference with the small bowel. Probably, mechanical interference with the biliary tract or gall bladder can be excluded. The reference of pain to the periumbilical area is characteristic of small-bowel lesions. Its colicky character and the fact that the patient was quite well between attacks are typical of transient, partial obstruction. The diarrhea, I think, can be explained by the fact that this pain stimulated peristaltic action. I do not believe the obstruction was ever complete. The most recent attack was somewhat severer, and for the first time, obstipation was noted. It is rather curious that no vomiting occurred with that attack, because with interference of small-bowel action, nausea and vomiting are quite prompt.

The patient had a weight loss of 20 pounds. That undoubtedly is significant and suggests, of course, that the lesion was a neoplasm.

The family history is irrelevant.

On physical examination, the mass first described as being in the epigastrium was smooth and nontender, no edge and no irregularity being demonstrated, which means that they did not believe it was the spleen. I suppose it might have been a cyst of the pancreas or omentum. Against a cyst of the pancreas is the fact that later physical and x-ray examinations placed the tumor mass lower in the abdomen, pressing on the sigmoid. This perhaps rules out cyst of the pancreas but does not rule out cyst of the omentum.

The blood pressure was not significant. The pulse was somewhat rapid at the time of admis-

1.
tial a
containing
No mel.
Bile was

sion to the hospital, showing an acutely ill man, and was perhaps a reaction to pain and discomfort. The hemoglobin was low, again perhaps suggestive of a neoplasm. The hemoglobin probably was not lowered by blood loss because we have no story of blood loss in the bowel movements. The white-cell count was 14,900, which is somewhat elevated. If the patient had an ulcerative lesion of the small bowel, with associated infection, that might account for it. The x-ray films are not particularly helpful. There were dilated loops of bowel and some gas in the dilated cecum, and the stomach was displaced upward—a picture of partial obstruction. The colon and cecum filled without delay. There was no evidence of lesions in the cecum, but there was extrinsic pressure on the cecum by a soft-tissue mass.

What was the soft-tissue mass that we assume to have been the cause of the trouble? I suppose that it might have been a cyst of the omentum, perhaps a tumor of small bowel. If so, it probably was not carcinoma, which gives a small cicatricial lesion as a rule, causing partial obstruction, and does not attain the size described in this case. Lymphosarcoma would be more likely to attain this size, and there might be more than one lesion and tumor of the small bowel itself causing intermittent obstruction; the soft-tissue mass described on x-ray study might be retroperitoneal lymphoma. I do not believe we need assume that there were multiple tumors, however. The symptoms were probably due to mechanical interference with the bowel by tumor. It might have been a cyst, possibly of the kidney, more likely of the omentum, and still more probably a tumor—a lymphoma or lymphosarcoma of the small bowel.

Perhaps Dr. Schatzki can give more information than appears in the written description.

DR. RICHARD SCHATZKI: The flat abdominal film shows the markedly dilated loops of small intestine described in the record. The cecum is moderately distended. I cannot see if the rest of the colon is distended. The soft-tissue mass is indefinite on the flat film; I cannot be sure of it. A

barium enema, however, shows it very clearly as displacing the sigmoid downward, without affecting the cecum. There is one region in the proximal transverse colon that, on the postevacuation films, looks a little narrow. I cannot imagine that the examiner would have missed a lesion of that size during fluoroscopy. I think the appearance is due to the enormous amount of fecal material that the patient had in his colon.

CLINICAL DIAGNOSIS

Intussusception?

DR. SOWLES'S DIAGNOSIS

Lymphosarcoma of small intestine.

ANATOMICAL DIAGNOSES

Polyp of ileum.

Intussusception.

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: This patient was explored. No definite preoperative diagnosis was recorded, although a note in the record at least suggested the possibility of recurring intussusception as the cause of the symptoms. At operation, a large sausage-shaped mass of small bowel, 75 cm. long, was found, which was an obvious intussusception. An attempt to reduce it proved impossible. It was necessary to resect the entire area, about 180 cm., as it turned out, of small bowel. At the head of the intussuscepting mass was an area where the mucosa of the ileum was markedly swollen, edematous and, at one point, frankly polypoid. There can be little doubt that intestinal polyps had been present for a considerable time, at least the two and a half years that the history covers, and had repeatedly acted as the focus behind which intussusception developed. On each of the earlier occasions, spontaneous reduction must have occurred.

DR. SCHATZKI: I looked carefully for intussusception in the flat film. Usually one can see some evidence of it. There was none, however.

MASSACHUSETTS MEDICAL SERVICE

LITERATURE concerning Massachusetts Medical Service — the Blue Shield — was mailed last Tuesday night to every licensed physician in Massachusetts. This included copies of the "Application of and Agreement with Participating Physicians" and the "Schedule of Surgical, Obstetrical and X-Ray Benefits."

Since many people in Massachusetts are anxiously waiting to participate in the plan and since the majority of industrial leaders are eager to provide their employees with an inexpensive and effective method of budgeting for unexpected surgical expense, all means to expedite actual operation of the Blue Shield should be provided. Furthermore,

medical societies in other states are watching with interest the development of this medical-service plan, which is still another example of Yankee foresightedness, cohesiveness and altruistic enterprise.

The mailing of contracts and fee schedules, scheduled for August, was retarded by the tremendous amount of detail necessary to make the plan operable. Because of this delay and because of the unsettled conditions prevailing in the Nation, all physicians are urged to sign both copies of the "Application and Agreement" and to return them immediately.

Further delay in the Blue Shield plan will lessen public interest and encourage the proponents of government-controlled medicine. The more rapidly Blue Shield begins to protect the health of Massachusetts wage earners, the sooner this very important health problem plaguing the mind of a war-conscious community will be solved. In view of the urgent need for an adequate scheme for the provision of medical care, let it never be said that the physicians of Massachusetts offered "too little — too late."

SALVATION ARMY APPEAL

THE Greater Boston Annual Maintenance Appeal of the Salvation Army will begin on September 28. More than two thousand volunteer workers will assist in the collection of \$250,000, the goal for 1942-1943. The twenty-seven cities that comprise the Metropolitan Division will be included in the drive.

At the opening dinner, to be held at the Boston Chamber of Commerce on September 29, the *Carrier Salvation* will be launched; the sister of an aviation ordnance man who died in action at Pearl Harbor has been selected as sponsor of the campaign ship. Governor Saltonstall, Mayor Tobin, naval, army and labor leaders and others will join in the launching.

The objective for this year, which is \$50,000 more than the goal in 1941, can be attained only through the greatest generosity on the part of those who contribute. The Salvation Army, which has done so much for the needy, must

raise its quota if it is to function in the difficult days ahead, when it may have to meet even greater demands for help because of shortages of fuel and other vital necessities.

The need is great, and there are few worthier causes. The appeal should inspire every public spirited citizen to do his utmost. Physicians, who have responded generously in former campaigns, are urged to continue to lead their communities in making the work of the Salvation Army possible.

MEDICAL EPONYM

ARGYLL ROBERTSON PUPIL

Although he credits Stellwag von Carion with the statement that tabes dorsalis and spinal paralysis may cause paralytic myosis, the account of the rigid pupil in his report, entitled "On an Interesting Series of Eye symptoms in a Case of Spinal Disease, with Remarks on the Action of Belladonna on the Iris, etc.," in the *Edinburgh Medical Journal* (14: 696-708, 1869), together with a later report, "Four Cases of Spinal Myosis; with Remarks on the Action of Light on the Pupil," in the same journal (15: 487-493, 1869), has served to affix permanently the name of Douglas Argyll Robertson (1837-1908), lecturer on diseases of the eye at the University of Edinburgh, to this phenomenon. The following quotation is from the earlier article:

On examining the eyes, I found both pupils contracted to little more than pin points, the right rather the smaller of the two. I could not observe any contraction of either pupil under the influence of light, but, on accommodating the eyes for a near object, both pupils contracted.

CASE HISTORY DEATH FOLLOWING PARTIAL SEPARATION OF THE PLACENTA AND VAGINAL DELIVERY

A twenty four-year old Polish woman began to bleed when approximately eighteen weeks in her second pregnancy, and continued to do so off and on until she was sent to the hospital in the thirtieth week. The past history was irrelevant, the only operative procedure being a cesarean section, which terminated her first pregnancy. After

the initial bleeding mentioned above, the patient was in bed the greater part of the time and was seen frequently from then on. The blood pressure and the urine remained normal; no vaginal examination was made. In spite of the frequent recurrences of moderate bleeding, the patient was not hospitalized until about the thirtieth week, when the bleeding became freer. No vaginal examination was made on entry, but five days later, labor started spontaneously. When it had progressed to the point where the cervix was dilated two fingerbreadths, there was so much free bleeding that delivery was attempted. It was a breech presentation, and a footling extraction was accomplished, apparently without difficulty. The patient, however, went immediately into shock and, despite transfusion, died half an hour after delivery.

Comment Undoubtedly, this patient was carried along from the eighteenth week for the purpose of obtaining a live child. In view of the previous cesarean section and the fact that the pregnancy, when labor started spontaneously, had reached the point of possible viability, it is strange that cesarean section was not immediately performed. Had it been done, this patient would not have died of hemorrhage. It is interesting that the death certificate stated the cause of death to be "placenta previa," but the details given by the visiting physician indicated that the bleeding came from a partially separated placenta. It is quite likely that if, as the record stated, delivery was attempted when the cervix was dilated but two fingerbreadths, this death was due to hemorrhage, possibly associated with rupture of the lower segment.

The handling of this patient from the beginning, although conscientious, was unintelligent, the method of delivery ill advised, and the death avoidable.

WAR ACTIVITIES

PROCUREMENT AND ASSIGNMENT SERVICE

The following release from Services of Supply, Office of the Surgeon General, has recently been forwarded to all corps area and state chairmen by the Procurement and Assignment Service.

* * *

The Surgeon General of the Army published detailed information concerning policies governing the initial appointment of physicians as medical officers on April 23, 1942. Necessary changes are given wide publicity, at his request, in order that the individual applicants, and all concerned in the procurement of medical officers, may know the status of such appointments.

The current military program provides for a definite number of position vacancies in the different grades. The number of such positions must necessarily determine the promotion of officers already on duty and, in addition, the appointment of new officers from civilian life. Such appointments are limited to qualified physicians required to fill the position vacancies for which no equally well-qualified medical officers are available. Such positions calling for an increase in grade should be filled by promotion of those already in the service, in so far as possible, and not by new appointments.

If this policy is not followed, it would definitely penalize a large number of well-qualified lieutenants and captains already on duty by blocking their promotions, which have been earned by hard work. In view of these facts, it has been deemed necessary to raise the standards of training and experience for appointment in grades above that of first lieutenant.

With this in view, the Surgeon General has announced the following policy, which will govern action to be taken on all applications after September 15, 1942:

All appointments will be recommended in the grade of first lieutenant with the following exceptions:

Captain. 1. Eligible applicants between the ages of thirty-seven and forty-five will be considered for appointment in the grade of captain by reason of their age and general unclassified medical training and experience.

2. Below the age of thirty-seven and *above* the age of thirty-two, *consideration* for appointment in the grade of captain will be given to applicants who meet all the following minimum requirements:

- a. Graduation from an approved medical school.
- b. Internship of not less than one year, preferably of the rotating type.
- c. Special training consisting of three years' residency in a recognized specialty.
- d. An additional period of not less than two years of study or practice limited to the specialty or both.

3. Eligible applicants who previously held commissions in the grade of captain in the Medical Corps (Regular Army, National Guard of the United States or Officers Reserve Corps) *may be considered* for appointment in that grade provided they have not passed the age of forty-five years.

Major. 1. Eligible applicants between the ages of thirty-seven and fifty-five *may be considered* for appointment under the following conditions:

- a. Graduation from an approved school.
- b. Internship of not less than one year, preferably of the rotating type.
- c. Special training consisting of three years' residency in a recognized specialty.
- d. An additional period of not less than seven years of study or practice limited to the specialty or both.
- e. The existence of appropriate position vacancies.
- f. Additional training of a special nature of value to the military service, in lieu of the above.

2. Applicants previously commissioned as majors in the Medical Corps (Regular Army, National Guard of the United States or Officers Reserve Corps) whose training and experience qualify them for appropriate

assignments *may be considered* for appointment in the grade of major provided they have not passed the age of fifty-five.

Lieutenant Colonel and Colonel. In view of the small number of assignment vacancies for individuals of such grade, and the large number of reserve officers of these grades who are being called to duty, such appointments will be limited. Wherever possible, promotion of qualified officers on duty will be utilized to fill the position vacancies.

Much misunderstanding has arisen concerning recognition by specialty Boards and membership in specialty groups. It will be noted that mention is not made of these in the preceding paragraphs. This is due to the variation in requirements of the different boards and organizations. Membership and recognition are definite factors in determining the professional background of the individual, but are *not* the deciding factors, as so many physicians have been led to believe.

The action of the Grading Board, established by the Surgeon General in his office, is final in tendering initial appointments. Proper consideration must be given such factors as age, position vacancies, the functions of command and original assignments. All questionable initial grades are decided by this board. Due to the lack of time, no reconsideration can be given.

There are in the age group from twenty-four to forty-five more than a sufficient number of eligible, qualified physicians to meet the requirements of the Medical Department. It is upon this age group that the Congress has imposed a definite obligation of military service through the medium of the Selective Service Act. The physicians in this group are ones needed *now* for active duty. The requirements are immediate and imperative. Applicants beyond forty-five years may be considered for appointment only if they possess special qualifications for assignment to positions appropriate to the grade of major or above.

MISCELLANY

TUBERCULOSIS AND INDUSTRY

Industrial health and tuberculosis in industry are topics of great concern to all nations at war. Britain, the senior partner of the United Nations by length of service, was confronted much earlier than we were by problems arising from the conversion of peace economy to war production. The following are abstracts from recent British publications.

INDUSTRIAL HEALTH

(Newman, G. *Britain Today* February, 1942.)

The recent reformation in the health and life of the industrial worker in Britain is one of the most impressive and remarkable chapters in the progress of preventive medicine. It records a development from disorder, neglect and confusion to regularity and discipline, and from arbitrary mismanagement to scientific planning. It has become physiologic, social and personal in objective. This is of national importance, for it affects five or six million men and women workers in the factories, and twenty million workers outside them. It sets a standard for all employment, and crystallizes British conceptions and traditions. It is perhaps the most popular of all public methods

of preventive medicine, and has in it the elements of a liberal education. It improves and fortifies the health of the workman,—his only capital,—increasing his dividend, lengthening his life and enlarging his opportunity and personality. It affects the whole man—his habits and character, his domestic life, his family and his home, as well as his workplace. It is a great school of citizenship and health education of body, mind and spirit.

The worker himself and not his factory environment is the vital factor. His fitness, capacity, endurance and willpower are the chief requirements in the prevention of the overstrain, fatigue and disharmony that may be the precursors of disease. This is the center of gravity.

SOME REFLECTIONS ON THE TUBERCULOUS IN INDUSTRY

(Mann, B. *Tubercle* 23 72-75, 1942)

For years, the aftercare attention meted out to post-sanatorium cases has been the Cinderella of the Tuberculosis Service. This has been due to a variety of factors. In the main, the results were less spectacular than those of the operating theater and hence never achieved the same popularity in the lay mind, and again with a floating peace-time unemployed population of about three million, healthy labor was at a premium.

Information about tuberculous disease or previous treatment at a sanatorium or dispensary should be made compulsory for all persons entering industry. This is the practice of military boards, and there appears no legitimate reason why this should not be incorporated into the civilian industrial life of the country. Such a measure would ensure the control of infection in the interests of the health of the community. Naturally such a course will occasion opposition. It will be argued that this represents an encroachment on the freedom of the individual. However, freedom would be an intolerable institution if it permitted a man indiscriminately to infect his fellow creatures with disease.

An extremely strong case can be made out in view of the recent extension of the defense orders making the treatment of scabies compulsory in the interests of national health. The extension of such a defense regulation to incorporate tuberculosis should prove a relatively simple legal measure.

MISS RADIOSCOPY IN FACTORIES

(Hall, A. S. *Lancet* 1 161, 1942)

Much has been written lately concerning the value of mass radiography of the chest, and reports, among others of investigations into the pulmonary disease of Australian recruits, British sailors and University College Hospital students are available but so far little has been done in this country with the ordinary unselected civilian population. Anyone who has wished to conduct such an examination must at once have become conscious of the many difficulties, of which lack of suitable apparatus and the reluctance of the population to submit to examination are the chief. Nevertheless, few doubt that these difficulties will soon be overcome.

X-ray screening of the chest was offered to the work people in two factories, the management allowing this to be done in working hours. In the first, 60 per cent and in the second, 97 per cent came for examination. Of 575 people examined in the first factory, 3 were found to be tuberculous. Of 795 examined at the second factory, 2 were known to have phthisis and 2 others were found to have active disease.

WEEDING OUT TUBERCLE

(Editorial *Lancet* 1 357, 1942)

Commenting on the above article by Dr. A. Stephen Hall, a later issue of the *Lancet* states in an editorial:

In each factory about 0.5 per cent of the workers had clinically significant tuberculosis. This percentage is lower than that found in similar mass surveys elsewhere, a common figure being between one and two per cent. The question therefore arises whether the examiner sees as much and as truly on the fluorescent screen as on the developed film.

In this matter of instrumental aid when employers and employees alike have been led to expect surveys which will wipe out tuberculosis it may be well to add a cautionary word. No diagnosis is ever made on a fluorogram; any doubtful or abnormal finding calls first for a full size radiogram and, should the abnormality be confirmed, a thorough physical overhaul. If the whole method is not to be discredited, and if hard ships and misery from faulty diagnoses are to be eliminated, as much thought must be given to the training of personnel as to the choice of apparatus.

If a worker submits voluntarily to examination he will naturally ask that he and his family are not to suffer financially while undergoing treatment for what, in his opinion might have healed at work. Tuberculosis is coming to be regarded more and more as a disease of economics.—Reprinted from *Tuberculosis Abstracts*, September, 1942.

CORRESPONDENCE

HUNTINGTON TUMOR CLINIC

To the Editor. The following letter has been sent to all physicians who have, in the past, recommended patients to the Huntington Memorial Hospital. I am sure that its publication in the *Journal* will give additional publicity to the new arrangement.

NATHANIEL W. Faxon, MD, *Director*

Massachusetts General Hospital
Boston

* * *

MASSACHUSETTS GENERAL HOSPITAL AND THE HUNTINGTON TUMOR CLINIC

The clinics formerly conducted at the Huntington Memorial Hospital have been transferred to the Massachusetts General Hospital. Records of former patients have also been transferred and are available. Letters have been written to many of the former patients telling them of the change and giving them new appointments. Notices informing physicians of the change have already been published in the *New England Journal of Medicine*.

The work is being carried on by former members of the staff of the Huntington Hospital, who are also on the staff of this hospital.

It has been the policy of the Huntington Hospital to care for patients of the small income and medium income groups. This same policy will be continued. The Massachusetts General Hospital has long conducted a tumor clinic and the Huntington clinics will be merged with the Tumor Clinic.

The Tumor Clinic will be divided, hereafter, into the Morning Clinic and the Afternoon Clinic. Former Huntington patients will be assigned to the appropriate clinic.

sponding clinic. Morning patients will enter through the Out Patient Department. Afternoon patients will be admitted directly to the Tumor Clinic through the Main Entrance, White Building.

New patients to either clinic should be recommended for admission by their physicians. Free patients or those who can pay only the usual small outpatient fee should be referred to the Morning Clinic. Patients who can pay a nominal sum (in excess of the usual outpatient fee) should be referred to the Afternoon Clinic.

Physicians should clearly state whether patients are referred for

Diagnosis or Consultation. In such cases, the patients will be returned to the physician with a following letter giving results and recommendations.

Diagnosis and Treatment. In such cases, diagnosis will be made in the Tumor Clinic and treatment will be carried out in the appropriate hospital department. When treatment is completed, patients may be returned for interval care to their physicians.

The organization of the Tumor Clinic is founded on the policy of having the clinic conducted as a joint project of the General Surgical Department and Radiological Department, assisted by consultants from the recognized medical and surgical specialties. Following this policy, the General Surgical Clinic and Radiological Clinic will be conducted daily, both morning and afternoon, but patients having lesions coming within the province of the various specialties should be sent on the following designated days:

Morning Out-Patient Clinic (9:30 a.m.)

Monday — Lymphoma and leukemia
Tuesday —
Wednesday — Urological and neurological
Thursday — Laryngological
Friday — Dermatological
Saturday — Gynecological

Afternoon Semi-Private Clinic

The General Surgical Clinic and Radiological Clinic will receive patients daily at 2 p.m., except Saturdays, when the clinics will be held at 9:30 a.m.

Patients for whom consultation in the various specialties is necessary should come the afternoon of the day that the appropriate specialty is cared for in the Morning Clinic, except that all gynecologic patients should come on Saturday morning.

NATHANIEL W. FAXON, M.D., *Director*

REPORTS OF MEETINGS

WILLIAM HARVEY MEDICAL SOCIETY

A regular meeting of the William Harvey Medical Society of Tufts College Medical School was held at the Beth Israel Hospital on May 8. Dr. Richard B. Cattell, of the Lahey Clinic, discussed "Cancer of the Colon and Rectum."

A consideration of some of the important fundamental anatomic and physiologic factors operating in this region aids an analysis of the subject. The right colonic contents are fluid and are teeming with bacteria, in contrast to the semisolid, relatively clean contents of the left colon. Certain difficulties are encountered because of the characteristics of the region. The bowel is thin walled, and this

makes anastomosis more difficult. The blood supply is from vessels that are essentially end arteries with few collateral vessels. The mobility of the colon decreases as the anus is approached, and the danger of injuring blood vessels and nerves in mobilizing the lower segments is thus increased. The lymphatic supply, which influences the kind and speed of spread of cancer, is much richer on the right than on the left side of the colon.

To realize the importance of this subject, one has but to know that 25 per cent of all cancer occurs in the gastrointestinal tract and that half of this is in the colon and rectum. It is twelve times as frequent in this region as inflammatory lesions. Sixty per cent of the malignant lesions occur in the rectum. Fifty-six per cent of the rectal lesions are in males, and 61 per cent of colonic lesions in females, the over-all distribution being about equal in the two sexes. The age incidence is about ten years older in cancer of the colon, in which 44 per cent of cases occur between sixty and eighty years of age. However, 16 per cent of the entire group studied at the Lahey Clinic were under forty years of age.

The pathogenesis of cancer in this region is better understood in many respects than that of cancer in the stomach. In the rectum, the presence of pre-existing polyps is of recognized significance. This condition may have a hereditary tendency, and congenital adenomatous polyposis is known to be a definitely precancerous condition. Polyps are found in about 2 per cent of the general population.

The commonest early symptoms of rectal carcinoma are bleeding, discomfort, tenesmus and change of bowel habits; those of the colon are bleeding, mucus, change of bowel habits, anemia, weight loss and vague abdominal complaints. Symptoms should never be attributed to the more benign of two possibilities in this region. The fallacy of this practice is borne out by the statistics, which reveal that 15 per cent of the patients proved to have rectal cancer had had operations for hemorrhoids within six months, and that another 15 per cent with the same diagnosis were treated medically. Change of bowel habits is present in 80 per cent of all patients with large-bowel cancers, but abnormal stools decrease from 86 per cent in rectal cases to 9 per cent in those with lesions in the right colon, whereas pain increases in exactly inverse proportion. Diagnosis should be made from the history, abdominal and rectal examinations, proctoscopy and sigmoidoscopy, barium and double contrast enemas, biopsy and exploratory laparotomy. The history is often irrelevant, but rectal lesions are within reach of the examining finger in 50 per cent of cases.

The preoperative care of such patients requires several days, and is divided into the restoration of the local and general physiology to as near normal as possible. Locally, the fecal material is completely removed by the most gentle method, and the bowel is kept clean. Generally, the patients are in sore need of fluids, vitamins and, possibly, transfusion. Cleansing of the bowel is best performed in one procedure and colonic irrigations are then carried out up to the day of operation. In cases of obstruction, the Miller-Abbott tube may be used to decompress the small bowel, but is only a temporary expedient and must be supplemented by operation within twenty-four to forty-eight hours to decompress the large bowel.

The technic of the operation for cancer of the large bowel is largely a matter of choice and experience of the surgeon. Surgery is the only sure way of curing such lesions. The operability of a lesion depends on early and accurate diagnosis, the extent of the lesion, the type of the operation and the experience of the surgeon. At the

Lahey Clinic, the Mikulicz obstructive resection is usually carried out for colonic lesions. In the rectum, where the sigmoid must always be sacrificed because its blood supply is embarrassed by the removal of the drainage areas from the rectum, either a one stage Miles or a two stage Lahey resection is carried out. During the last fifteen years, the operability has increased from 47 to 89 per cent, but the mortality has been reduced from 36 to 7 per cent. Thus although more borderline cases come to operation, improved preoperative care and operative technique have markedly decreased the mortality.

The prognosis of large bowel cancer is variable. If colonic lesions are confined to the bowel, there are 90 per cent five year cures, but this drops to 50 per cent when the regional lymph nodes are involved. When the lesion is removable, the curability is 45 to 50 per cent. The total salvage is 33 per cent but many patients who are operated on are greatly benefited. In the Mikulicz operations on the colon, the mortality is less than 3 per cent whereas Mikulicz operations on the whole have a 17 per cent mortality. This is at least partly explained by the better mobility of the colon, which allows for more radical excision of the malignant growth. It was pointed out that although 60 per cent of the patients with cancer of the right colon have enlarged regional lymph nodes many of these may be inflammatory. This may be favorable for the prognosis but should not influence one's judgment of the amount of mesentery to be removed.

BOSTON CITY HOSPITAL

The third of the series of lectures sponsored by the Boston City Hospital House Officers Association was held at the hospital on May 12. Dr Edward D Churchill discussed "The Problems of Wartime Thoracic Surgery."

Most traumatic chest wounds do comparatively well if hemorrhage is not rapidly fatal and if there is not undue tampering with the wound at the first-aid stations. Since it is impractical, if not impossible to assemble a competent thoracic team in the combat area, only a minimal amount of actual surgery is carried out there. First aid is aimed at the arrest of hemorrhage from the wound, the physical correction of the disturbed cardiorespiratory physiology and the prevention of infection.

The second of these is by far the most essential in chest wounds and is peculiar to this region. In the so-called sucking wounds, a large defect of the thoracic wall causes an open pneumothorax and mediastinal flutter. These factors result in cardiac as well as respiratory embarrassment, and large wounds of this type are rapidly fatal if uncorrected. Small wounds, even of both sides, are compatible with life. Treatment of such wounds is aimed at closing the defect as thoroughly and quickly as possible by any means. Skin flaps, if available, may be sutured, or some such substance as cellophane may be employed. Above all, the pleural cavity should not be packed with gauze, for this is unnecessary for the restoration of physiology and the gauze is poorly tolerated. One of the sulfonamides in the wound before closure is desirable.

The second important problem concerns tension pneumothorax or the accumulation of air under pressure in the pleural cavity. This may occur in the previously mentioned large wall defects after closure if there is injury to a bronchus, or if a penetrating wound allows escape of air from a bronchus. In either event, air enters the pleural space at each expiration and is stored under increasing pressure, with resultant respiratory embarrassment. Such patients are cyanotic and have characteristic

grunting respirations. Subcutaneous emphysema is a common complication, but needs no specific emergency treatment if the underlying pleural tension is properly handled. This merely requires the making of a hole in the chest wall with whatever means is available. Preferably, a trocar and small catheter connected to a water-sealed trap should be used. Another complication, which demands immediate therapy, however, is the backflow of interstitial air around the bronchi to cause mediastinal emphysema. The first indication of its presence is seen in the suprasternal notch. Its presence disturbs particularly the return of blood to the heart by compressing the great veins, and there is subsequent decreased cardiac output and shock. The treatment of this serious emergency is the performance of mediastinotomy through a collar thyroid incision. This starts like a low tracheotomy except that, instead of opening the trachea, a finger is inserted beneath the sternum.

The third serious problem results from multiple fractured ribs. Crushing injuries not infrequently cause fractures anteriorly and posteriorly, with a mobile fragment between. The same effect is found in bilateral fractured ribs. In either event, there is paradoxical movement of this mobile fragment, with subsequent respiratory embarrassment proportional to the amount of displacement of the fragment. This is a difficult condition to treat, especially since respirators—the ideal thing—certainly will not be available in field hospitals. Strapping often makes the pain and disability worse, but may be tried temporarily. Relief is sometimes afforded if the patient lies on the affected side. Traction may be improvised by the use of such things as skin towels on the ribs and the consequent steadying of the fragment.

Finally, there is the question of slowly progressive hemorrhage, such as that occurring in a lacerated lung. Bleeding from major vessels is usually rapidly fatal. Since the pleural cavities can contain as much as 5000 cc of fluid it is obvious that fatal hemorrhage may occur before there are any signs of mechanical interference with respiration. Therefore, the degree of hemorrhage should be judged by the usual criteria employed in general. Treatment is not standardized. The blood may be aspirated, and an equal amount of artificial pneumothorax may be substituted in an attempt to allow the bleeding point to seal itself by putting the lung at rest. The use of such aspirated blood for autotransfusion is impractical, and may even be dangerous in war wounds, in which contamination is frequent. If nothing is done at the time, there may be 1000 to 1500 cc of blood in the pleural cavity, augmented by an additional amount of serous exudate from the trauma. This may demand aspiration to relieve respiratory distress and if so air should be reinserted to prevent further hemorrhage. If the amount is small, nothing need be done. If the accumulation is going to be removed at a later date, it should be carried out gradually or with the substitution of air. Because the thick blood may create a mechanical problem for aspiration, a trocar and catheter (No 24 to 26) may be used. This should be left in place for only four to six hours, however, and should not be left as a drain. In general, an uninfected hematoma of this region should not be drained in the ordinary sense. Since the very presence of hemithorax is sufficient cause for a moderate fever and a minimal leukocytosis, a microscopic or cultural examination of the material removed is necessary to establish the diagnosis of sepsis. Despite older theories, it is now considered feasible in low grade infections with no constant source of organisms from the lung or chest wall to carry out pri-

mary closure aided by the use of the sulfonamide compounds locally and systemically.

The definitive treatment of chest wounds will be successful and can be carried out only where there are experienced anesthetists. A general surgeon can do a good piece of work with the help of a good intratracheal anesthesia; a competent anesthetist can accomplish this with inadequate equipment, whereas the inexperienced man is never certain even with the best equipment. In injuries of the lung, the patient should be kept somewhat dehydrated to prevent pulmonary edema, and in hemoptysis, the use of blood or blood-substitute transfusions is postponed as long as possible.

Dr. Churchill discussed the types of drainage and their indications. Open drainage, or rib resection, allows free entrance of air. This is used only when there is an encapsulated accumulation of pus and when there are firm adhesions between the rest of the lung and the pleura. Constant close drainage, or an intercostal tube, allows the escape of fluid and air but not the entrance of air. Some form of valve, preferably a water-sealed valve, is employed. This is used to relieve a continuing pressure pneumothorax, and should be used only rarely in a rapidly increasing infectious exudate. Intermittent closed drainage is similar, except that the tube is clamped and only periodically aspirated. It may be used occasionally postoperatively or when there is no way of arranging an escape valve. It may also be employed for forty-eight hours following extensive débridement to guard against tension pneumothorax and to give warning of hemorrhage or sepsis; if there is no septic exudate at that time, it is removed. But many surgeons prefer primary closure when the patient is not under constant personal observation, for otherwise the tube may be left too long or mishandled. One must rely on somebody en route to insert a tube if necessary, and the sulfonamides must be used to make the procedure safe.

Empyema was too common an occurrence during World War I. Before any therapy is carried out, a careful diagnostic thoracentesis is done. If foul pus is obtained, there is only one course—immediate open drainage. If such pus is not encountered, cultures are made, and treatment is decided on accordingly. In the early stages of acute spreading pleuritis, the process is a cellulitis, just as in early cases of peritonitis. In such cases, drainage is more harmful than advantageous, especially in the chest, where there is the additional danger of pneumothorax. Only when an abscess has formed should drainage be carried out, and then by rib resection at the dependent spot. The commonest mistakes are for the diagnostic thoracentesis to be made too low and the rib resection too high.

Retained foreign bodies in the lung or pleura should not occasion any immediate worry. They are best left alone unless thoracotomy and débridement are necessary. Smooth metal bodies seldom cause subsequent trouble, but jagged shell fragments not uncommonly lead to suppuration.

BOOK REVIEWS

Foundation for a Science of Personality. By Andras Angyal, M.D., Ph.D. 8°, cloth, 398 pp. New York: The Commonwealth Fund, 1941. \$2.25.

This book is a profound study of personality. The author is a philosopher as well as a physician. He attempts to show that the psychology of personality can be a science, although it is not yet one. Dr. Angyal goes

back to the beginning and borrows much from Aristotle. He applies Aristotelian attitudes to new phenomena in the field of psychiatry. How well he carries out this in his book must be determined by the individual reader.

This is a very complicated and thoughtful volume that most readers will find slow going. Before it could be useful to the clinician, it would have to be thoughtfully digested and reinterpreted. It will never be a book for the general reader, but will be interesting to the educated physician who likes occasionally to think.

Cerebrospinal Fever. By Denis Brinton, D.M. (Oxon), F.R.C.P. (Lond.). 8°, cloth, 163 pp. Baltimore: Williams and Wilkins Company, 1941. \$3.00.

Few serious diseases have been more affected by chemotherapy with the sulfonamide group of drugs than cerebrospinal fever. The mortality of 50 per cent in World War I has been reduced to 10 per cent in the present conflict. With a few pills, patients with a dangerous and fatal disease are now usually well in a week or less. Rules of dosage are needed, and complications of treatment must be avoided; serum therapy and repeated lumbar puncture, however, are considered obsolescent. This excellent monograph, timely in its appearance, gives a physician all that he needs to know about one of the miracles of modern medicine. The book should be in every Army and Navy hospital and in the hands of every physician called on to treat cerebrospinal fever. Each section of the subject is clearly stated, and the book contains an adequate list of references and an index. The few illustrations show the complicating rash.

Workmen's Compensation and the Physician: A manual for the use of general practitioners and insurance carriers. By Henry H. Jordan, M.D. With a discussion of traumatic neuroses by Paul H. Hoch, M.D. 8°, cloth, 180 pp. London: Oxford University Press, 1941. \$3.00.

The general practitioners and representatives of insurance carriers do not always see eye to eye, regarding the importance of rendering certain medical services to an injured employee. This difference of opinion causes them to waste valuable time in litigation and keeps the industrial-accident boards busy. These conflicts do not add to either the comfort or the well-being of the injured employee. To remedy this situation, Dr. Jordan, equipped with an eighteen years' experience in workmen's compensation and in his capacity as a referee in orthopedic and traumatic surgery, wrote the present manual. Since impartiality seems to have been his guide in the treatment of every phase of this subject, this book is likely to bring about a better understanding, on the part of all concerned in workmen's compensation, of their common problems.

The treatment of disabilities arising "out of and in the course of employment" is discussed from all angles. Is there a "causal relation" between the confirmed incident during the employment and the pathologic condition causing the disability? Could the sequence of events leading to the accident directly or indirectly have produced the pathologic changes or at least influenced to a major degree a pre-existing major condition? Is there any unintentional exaggeration or malingering or distortion of the true picture, willfully carried on to obtain greater remuneration? What is the most effective method of treatment—a matter of great concern to patient and doctor alike? (Here, paradoxical as it may seem, the author points out that the more expert physical-therapy measures or costly orthopedic

appliances, properly handled, not only prove a blessing to the patient but in the long run constitute a great financial saving to the insurance carrier in the settlement of the claims, and to this end, brief but fairly complete chapters are devoted to the physical therapy and the orthopedic appliances. Is the disability partial or complete? Is it temporary or permanent? What will it mean to the patient in terms of ability or inability to engage in gainful occupation? All these questions and many more are answered by the author, a competent man, who has reviewed some thirty thousand cases of workmen's compensation and has developed a keen sense of values and fair judgment.

This book is a distinct addition to a rather meager collection of works on an important subject.

The 1941 Year Book of Public Health Edited by J. C. Geiger, MD, DPH 12", cloth, 544 pp., with 20 illustrations Chicago The Year Book Publishers, Incorporated, 1941 \$3.00

The purpose of these publications is being slightly missed. The year book idea is excellent,—and this one is well written,—but its purposes and values might profitably be restudied. It is inevitable that a book written for physicians, administrators, hospital and school authorities, public health nurses and others should contain much material that physicians alone are not interested in and that they should not be led to buy or read unless they can feel assured that they are being brought really up to date in their own spheres of activity and responsibility.

The reviewer is disturbed by the omission of what seems to him vital material relating to the period covered. For example, rheumatic fever is given ten pages, but the chemoprophylaxis of rheumatic recurrences is not mentioned. In the reviewer's opinion, the most promising contribution of the decade has thus been overlooked. In the field of child nutrition, it is not necessary to be told again that the child of today is the man of tomorrow when instead one might be reminded that a simple method of plotting physical fitness from two to twenty years of age has at last been devised. Both these subjects were presented and editorially commented on in the *Journal of the American Medical Association*, so that their omission will be noted by physicians who keep themselves informed; those who do not keep themselves informed will be more entertained than instructed by buying and reading the book.

The physician needs a year book in the field of disease prevention, but it need not be so voluminous as this and should be much more comprehensive. As for the others,—administrators, hospital and school authorities and public-health nurses,—the reviewer will not presume to speak, he hopes that they will not be discouraged by his own disappointment.

An X-Ray Atlas of Silicosis By Arthur J. Amor, MD (London), MSc (Wales). With translation of the legends into French by Robert E. Horne, MA, and a foreword by Sir Wilson Jameson, MD (Aberdeen), FRCP 4", cloth, 206 pp., with 72 plates Baltimore The Williams and Wilkins Company, 1941 \$8.00

This atlas of silicosis consists mainly of reproductions of x-ray films depicting the various stages of silicosis, silicosis as found in various industries and complications of silicosis, as well as films for differential diagnosis. There are five short chapters dealing with the nature of silica dust and the pathology of silicosis, a short discussion on

the radiologic examination of the lungs and the clinical manifestations, and a few remarks on the prognosis.

Unfortunately, the author discusses silicosis in various industries, such as iron ore mining, tin mining, slate quarrying and pottery, giving the impression that the films are characteristic for the industry. The statement is made under slate quarrying that calcification at the hilum is almost specific to that industry. This statement can hardly be justified in view of the many variable factors that play a part in this disease, such as infection, personal resistance and the degree of tuberculosis that may complicate the picture.

The descriptive material is fairly adequate, although many statements are rather dogmatic and lack clarity. Thus, the author states that in many obvious cases of pulmonary tuberculosis, tubercle bacilli are not found in the sputum, but he fails to state whether or not culture growths and guinea pig inoculations of the sputum were included. In this country, Dr Pinner and his associates have shown that tubercle bacilli can be demonstrated in over 90 per cent of clinical tuberculosis and that a negative sputum in the presence of pulmonary disease is significant provided culture or guinea pig inoculations have been included. Much confusion still exists in the minds of many physicians about when early silicosis begins and the exaggerated lung markings of the normal chest ends. At best, the question of silicotuberculosis, or tuberculosis without silicosis, is still subject to individual interpretation.

The atlas, nevertheless, is a welcome addition to the growing literature on silicosis. The book should be of value to the roentgenologists and especially to the physician interested in the ever increasing and complicated problems of silicosis.

A Manual of the Treatment of Fractures By John A. Caldwell MD 8", cloth, 150 pp., with 76 illustrations Springfield, Illinois Charles C Thomas, 1941 \$3.50

This manual, written primarily for medical students, house officers and general practitioners, fills a distinct need for a concise description of the accepted methods of treating the usual types of fractures. Many excellent and exhaustive books have been written about fractures, but no small compendium has as yet given the essentials of treatment so clearly and briefly. The book is illustrated with good line drawings, and each chapter is supplemented by a number of references to medical literature for those who wish further information.

The Furtherance of Medical Research By Alan Gregg, MD 8", cloth, 129 pp. New Haven Yale University Press, 1941 \$2.00

Few can be so well qualified to discuss the furtherance of medical research as Dr Alan Gregg, director for the medical sciences at the Rockefeller Foundation. The author will have the hearty support of all thinking people in his belief that the growth, indeed the survival, of interest and support for medical research depends on widespread understanding of what it is and what it is worth. He further argues with commendable vigor that in democracies the public attitude toward research plays a major role in making truth useful. The lectures that compose this book were given at Yale University under the Dwight Harrington Terry Foundation. The first lecture is entitled *Medical Research Described*, the second, *Universities and Foundations*, and the third, *The Medical Research Worker*. At the end of the book,

Appendix I concerns an outline docket item, and Appendix II is an outline for presenting a proposal for a capital grant for building an institute. The book is delightfully written and interspersed with witticisms and appropriate historical references. It is the reviewer's opinion that this book should be read by every medical student and that all librarians should draw special attention to it for study, not only by students but by faculty members.

Maude Abbott: A memoir. By H. E. MacDermot, M.D., F.R.C.P. (Can.). 8°, cloth, 264 pp., with 10 illustrations and 1 portrait. Toronto: The Macmillan Company of Canada, Limited, 1941. \$2.50.

Maude Abbott's list of interests and accomplishments is in itself enough to place her in the forefront of women who have become physicians. She was a pioneer in education for women and their training in medicine. A great contributor to medical museums and a frequent stimulator of historical research in others, as well as a distinguished contributor to the history of medicine in Canada, she is of course noted mostly for her extensive work on congenital heart disease; but, as has been pointed out, in addition to her efforts in this field, her most important contribution was the vital stimulus given to others by a spirit that was indefatigable. Few persons have set a more rapid pace than Maude Abbott, and memories of her are always associated with the tremendous pressure of activity and an abundance of work at hand. She seemed never to relax and even at the age of seventy was actively engaged in research. She applied for a fellowship with the Guggenheim Foundation in anticipation of an elaborate revision of her abstracted cases of congenital heart disease when she had already passed the age of three score years and ten.

Dr. MacDermot has written an excellent biography of one of the most unusual and stimulating persons in recent medicine. Maude Abbott stands out as a beacon, the greatest woman physician of Canada and one of the outstanding physicians in her generation. The biography is intimate, stimulating, well written and finely documented. In it, one finds an inspiration second only to that which could be given by the subject herself. To have known Maude Abbott was a privilege given to many during her long career. To those who knew her and to the many thousands of physicians and students who will follow, this biography will be welcome.

A Text-Book of Neuro-Anatomy. By Albert Kuntz, Ph.D., M.D. Third edition, thoroughly revised. 8°, cloth, 518 pp., with 307 illustrations. Philadelphia: Lea and Febiger, 1942. \$6.00.

This standard book has long made a name for itself in the field of neurologic literature. A few changes have been made in this new edition, but the general form has not been altered.

A Textbook of Surgery. By American authors. Edited by Frederick Christopher, M.D. Third edition, completely revised and reset. 4°, cloth, 1764 pp., with 1538 illustrations. Philadelphia and London: W. B. Saunders Company, 1942. \$10.00.

This single-volume text on surgery has become, since 1936, when the first edition was published, the standard reference book of its type in America. More than just a student's book, this is a work for surgeons, written by men of wider clinical experience and leaders in progress.

The third edition contains new material on war injuries and sections on the applications of the sulfonamide

group of drugs. The book is, indeed, as the editor marks in his new preface, "an up-to-date, practical treatise on surgery."

Association for Research in Nervous and Mental Diseases. Volume XXI. The Diseases of the Basal Ganglia. Proceedings of the Association, December 20 and 21, 1941, New York City. 8°, cloth, 719 pp., with 268 illustrations and 15 tables. Baltimore: The Williams and Wilkins Company, 1942. \$10.00.

Nineteen chapters, by various authors, deal with the anatomy, physiology and clinical aspects of diseases associated with the basal ganglia of the brain. Much of the book is highly technical, particularly the sections on anatomy. This part is authoritative and up-to-date. The clinical chapters are of less value, although the drug treatment of paralysis agitans is well handled. The value of surgical treatment of disease of the basal ganglia is still uncertain. The last few chapters emphasize this uncertainty.

The book is well edited and handsomely published. It forms the twenty-first volume of the publications of the Association for Research in Nervous and Mental Diseases.

A Manual of Pharmacology, with Its Applications to Therapeutics and Toxicology. By Torald Sollmann, M.D. Sixth edition, entirely reset. 4°, cloth, 1298 pp. Philadelphia: W. B. Saunders Company, 1942. \$8.75.

This new edition, the sixth, of a standard work, first published in 1917, is somewhat disappointing. Errors have crept in, the current literature is not always carefully surveyed, and the book has lost something of the authoritative character associated with the older editions. It is still useful, but the reader is warned to beware of reference citations without personal verification.

Communicable Disease Nursing. By Theresa I. Lynch, R.N., Ed.D. 8°, cloth, 678 pp., with 156 illustrations and 5 color plates. St. Louis: The C. V. Mosby Company, 1942. \$3.75.

This is a carefully written, exhaustive manual of detailed instructions in the technic of elementary nursing procedure. It should serve as a valuable textbook for nurses who are being trained in the care of patients with communicable disease.

Chinese Lessons to Western Medicine: A contribution to geographical medicine from the clinics of Peiping Union Medical College. By I. Snapper. With a foreword by George R. Minot, M.D. 8°, cloth, 380 pp., with 132 illustrations. New York: Interscience Publishers, Incorporated, 1941. \$5.50.

It is always a welcome privilege to make ward walks with a distinguished clinician. This book transplants the reader to the wards of the Peiping Union Medical College Hospital. The author has been recognized as a clinician with an erudition born of intensive study at the bedside and a wide knowledge of the literature.

The diseases indigenous to the locale are taken up. Primary among these are the various avitaminoses, tuberculosis, which is quite rampant, infectious diseases, such as kala-azar, and acute opium poisoning, to mention but a few of the widely diversified group of subjects.

In view of present world conditions, this volume should prove particularly valuable to those who may find themselves intimately associated with our ally.

NUMBER 14

CESAREAN SECTION IN MASSACHUSETTS IN 1941

ROBERT L. DeNORMANDIE, M.D.

BOSTON

THIS report is the fifth of the five-year study of cesarean sections sponsored by the Massachusetts Department of Public Health and the section of Obstetrics and Gynecology of the Massachusetts Medical Society.

The usual questionnaires were sent to one hundred and sixty-four maternity hospitals, and replies were received from all.

* * *

In Massachusetts in 1941, there were 71,234 live births and 1796 stillbirths, a total of 73,030. Of these, 63,266 were reported to us as having occurred in hospitals. Two thousand four hundred and thirty-six cesarean sections were performed. One abdominal pregnancy is not included in the statistics. There were 14 hysterotomies, making a total of 2450 abdominal deliveries.

The incidence in 1937 was 1:30.3, in 1938, 1:28.7, in 1939, 1:32.2, in 1940, 1:29.2, and in 1941, 1:29.8.

Little comment is necessary regarding Table 1, except that the number of extraperitoneal operations and of Porro operations increased, being respectively 44 and 41. Six elective and 25 emergency Waters operations were performed. Three patients died in the emergency group; these are commented on below. Of the other types of extraperitoneal operations, 3 were elective and 10 emergency; none of these patients died. All the emergency operations followed long, ineffectual labors. Some of these patients were undoubtedly neglected, but others were under competent supervision of well-trained physicians all the time, and why they were allowed to remain in labor as long as they were is difficult to understand. In at least several of these cases, sulfanilamide was used in the abdominal cavity, and the patients recovered. In the extraperitoneal group, 3 sections were done following failure of operative attempts by vagina. In 1 case, the patient was in labor for twenty-four hours and was trans-

fused four times, and the wound became septic and drained for thirty-seven days. The baby was stillborn and hydrocephalic.

Of the Porro operations, 14 were done for fibroid uterus, 5 because of ruptured uterus, 4 following

ether is still the first choice, and the use of cyclopropane has dropped.

Table 4 shows the reported indications for operations in which the baby died. As in previous years, the greatest number of babies were lost from placenta previa and separated placenta. It should be noted that 18 babies were lost following previous sections. The reason for these deaths in almost all cases was that the operation was done because the patient went into labor or ruptured her membranes at about the seventh month. Some of the babies,

however, were full term, and it is difficult to explain why they were lost, although one must always realize that even in delivery by vagina a certain number of infants die. It is to be expected that many of the babies in emergency sections die because of hard labor or for other good reasons that can hardly be blamed on the operation. But the loss of so many babies in elective sections raises the question whether the technic was satisfactory

or whether the operations were done at the proper time in the gestation.

Table 5 presents the detailed indications for cesarean section. The same comment is made on this group of cases that has been made in the other reports.

In many cases of placenta previa, the patient could have been delivered exactly as well if not better by vagina, and it is hard to believe that the

indications "contracted pelvis" and "disproportion" were valid when the babies were found to weigh only 5 or 6 pounds. This happened in too many cases. One cannot help believing that it seemed to the operator the easiest way to terminate a slow labor.

There were 8 cases of eclampsia, with 4 deaths. Again, it is obvious that the prenatal care of these women was inadequate. Whether it was the fault of the patient or of the doctor in charge, there is no way to determine, but the loss of 50 per cent of the cases is surely a very poor result.

Few comments are necessary on the remaining indications. In this, as in previous reports, the indication "following operative attempts" has had to be recorded. Criticism must again be made of surgeons who perform a cesarean section simply at the request of the patient or for purposes of sterilization, without any other adequate reason.

It is interesting that in a case of spontaneous rupture of the uterus, the patient had had in a previous pregnancy an inverted uterus for which a Spinelli operation was done. She went through this pregnancy satisfactorily until near term, when the uterus ruptured in the line of the old Spinelli incision. She was immediately operated on and recovered.

In 5 cases, the recorded indication was "twins." This does not mean that these were the only cases of twins, but in these cases no other indication was given. It is doubtful if these operations were in any way necessary. It should also be noted that in 1 case a large baby was suspected, no x-ray film was taken, a cesarean section was done, and twins were delivered.

Every year, there are a number of cases for bizarre indications on which there seems no need for further comment.

Table 6 presents a summary of the 52 cases in which maternal death occurred, a mortality rate of 2.1 per cent. As in previous years, emergency operations accounted for the greatest number of deaths. The fact that elective operations resulted

in previous years, the division has been nearly equal.

Of the 3 Porro operations resulting in death, all were done because of bleeding, and 2 were complicated by the presence of placenta accreta. Two of these deaths are classified as due to hemorrhage, and 1 is assigned to sepsis.

The three Waters operations in the group of maternal deaths were done after long labors with ruptured membranes. One death is assigned to

FIGURE 1. Maternal Deaths in 16 Elective Cesarean Sections.

pulmonary edema, 1 to hemorrhage, and 1 to sepsis. The patient who died from hemorrhage was transfused eight times.

Figures 1 and 2 present the indications for operation and the causes of death in the elective and the emergency cesarean sections, respectively.

Of the 16 deaths following elective sections, 6 were from sepsis. Criticism must again be directed at the surgeons who lost these 6 cases. Of the 3 toxemic cases, 1 patient died of an embolus and the other 2 might well be classified under the toxemias, but in 1 of these the patient failed to excrete any urine and the physician regarded the cause of death as uremia.

The patient who died from intestinal obstruction had a large hernia as the result of a previous cesarean operation. The present operation was performed without complications. During convalescence, there was some vomiting, and a Levine tube was used without relief. The vomiting became worse. Apparently, a pneumonia developed

in the death of 16 patients shows that cesarean section is not always a safe procedure. In these 52 cases, 40 babies lived, and 12 were lost. In 1941, the deaths following classical sections were far more numerous than those after the low type of opera-

in the right base, and the patient died without relief of the intestinal obstruction. Autopsy showed that there was incarceration of loops of the small intestines resulting from the old hernia. It seems from the facts presented in the questionnaire that this case was not handled intelligently.

The death from hemorrhage occurred in a patient with placenta previa who had had nine previous normal deliveries and who had been in the hospital for fifty days, spotting occasionally.

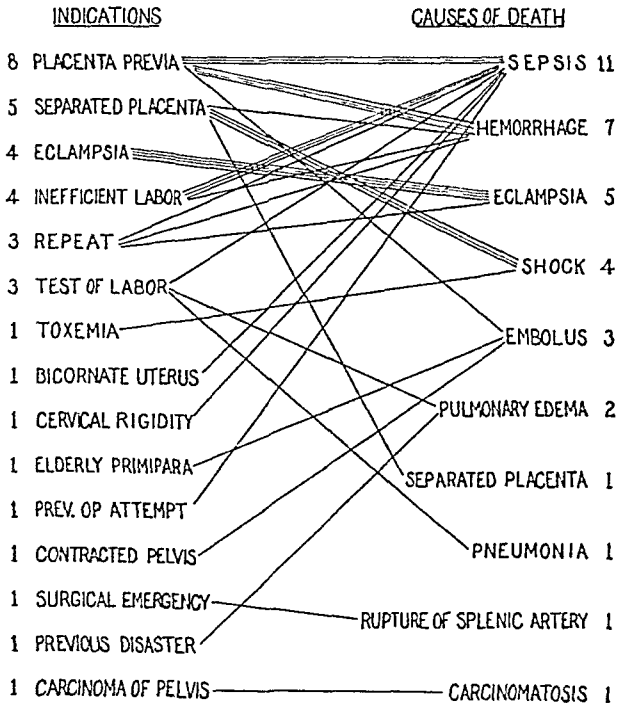

FIGURE 2. Maternal Deaths in 36 Emergency Cesarean Sections.

Operation was finally decided on, and an elective section was done. The patient went into shock and died of hemorrhage. It seems hardly reasonable to have delayed operation for fifty days with more or less spotting occurring all the time. This surely must be regarded as a preventable death.

The case in which the indication is "not reported" is the only case of death in the five-year study on which we have been unable to secure an intelligent, complete report. Repeated efforts to obtain the facts in this case have been unsuccessful. The questionnaire was returned with the statement that it was an elective section and that the cause of death was "acute cardiac dilatation precipitated by vasomotor collapse." No comment on this diagnosis is necessary.

The patient with blood dyscrasia had an unusual blood picture, bleeding from the mucous

membranes and vomiting a large amount of blood. In spite of all treatment, she steadily failed.

Of the 36 deaths that followed emergency sections, sepsis again was responsible for the greatest number. One case in this group that warrants examination had as an indication "cervical rigidity." This patient, a forty-year-old primigravida, was said to be two weeks overdue, and for this reason, an attempt at induction of labor was made. Castor oil and pituitary extract were given in small doses, but the attempt was unsuccessful. Two days later, the membranes were ruptured manually, and a Voorhees bag was introduced with considerable difficulty. It was stated that the cervix was hard to dilate, and that the bag promptly came out. The patient had only indefinite labor, and following a consultation a cesarean section was decided on. A low transverse section was done. At the time of operation, the temperature was 99.6°F. The following day, it rose to 101°F., and climbed steadily until death occurred from sepsis on the eighth postoperative day. This appears to be a typical case of meddlesome midwifery. There was obviously no indication to induce labor, for the patient was perfectly well and the cervix was not favorable for induction. The only reason given was that she was two weeks beyond her calculated date. On failure of medical induction, mechanical induction was attempted. It was obvious when the Voorhees bag was expelled so quickly that the surgeon had not placed it within the uterus. This case is a tragic illustration of the fact that so long as physicians attempt to induce labor without the ability to judge whether or not the patient is ready for induction, bad results are inevitable. It is cases such as this that keep the death rate higher than necessary.

Two deaths, those with indications "surgical emergency" and "carcinoma of the pelvis," cannot be attributed to obstetric complications.

* * *

The results obtained in the cesarean sections in 1941 were excellent, as they were during the entire five-year study. However, they could and should have been better, for it is obvious that many of the deaths were preventable. Far too many deaths are still occurring from sepsis. There is obviously altogether too much haphazard operating. This situation can be improved only by careful study of each case and the mapping out of as definite a procedure as possible for its management. As has been said repeatedly in these reports, cesarean section is an easy way out of a difficulty, but too often has fatal results.

CARCINOMA OF THE BRONCHUS*

GEORGE W. HOLMES, MD†

BOSTON

THIS presentation is based on a review of the recent literature, a study of the 158 proved cases treated at this hospital and reported by King,¹ Churchill² and Adams and Davenport,⁴ and an examination of the records of 68 additional cases seen from November 1, 1940, to March 1, 1942, inclusive. The latter group was selected for more intensive study because it was made up of patients who were seen during a period when the methods of diagnosis and treatment were better understood and when supervoltage x-rays were available for the treatment of nonsurgical cases.

Since early, correct diagnosis is of paramount importance and since the number of patients reaching the surgeon at a time when surgical cure is possible is very small, I have limited this discussion largely to the roentgenologic findings in the early stages of the disease and to its treatment with the roentgen rays.

GENERAL CONSIDERATIONS

Cancer of the bronchus is not a rare disease, occurring about as often as cancer of the rectum. The present operative mortality is not formidable, being approximately that of cancer of the stomach. Five year surgical cures have been obtained in 4 to 6 per cent of cases. In this series, there were no five year cures by irradiation although several cases are reported in the literature, however, this method of treatment offers much in the way of relief of symptoms and in some cases of definite prolongation of life.

The progress of the disease is usually rapid, its duration from the date of the first symptom to death being a matter of months rather than years. For this reason, early diagnosis and prompt treatment are imperative, the delay of a month before institution of treatment may mean the difference between success and failure. It is a disease of men (rarely of women), usually in the so called 'cancer age'. The early symptoms and signs are not characteristic and may be entirely absent. The late symptoms are those of its complications, and when they occur the disease is, as a rule, incurable.

Roentgenologic examination often gives the first clue to a correct diagnosis and should be so conducted that all possible information is obtained.

The responsibility of the roentgenologist in these cases is great. The diagnosis is established by bronchoscopy, thoracoscopy or surgical exploration, and these procedures should not be delayed when the clinical and roentgenologic findings suggest early bronchial cancer. The type of tumor, as determined from a specimen taken at bronchoscopy, is of great consequence in the decision of what form of treatment should be undertaken. Oat cell and undifferentiated carcinomas are radio sensitive tumors and usually disappear locally under this form of treatment, whereas the surgical results in the same groups have been uniformly bad. Adenomas and the slower growing types of malignant tumors are radioresistant, but often show excellent results when treated surgically. Consequently, a biopsy should be obtained when ever possible. Advanced cases with lung necrosis or empyema are probably made worse by intensive irradiation and should be treated surgically, if at all.

STATISTICAL DATA

In the 68 cases observed since November, 1940, histologic classification was as follows: epidermoid carcinoma, 26 cases, adenocarcinoma, 4 cases, oat cell carcinoma, 8 cases, undifferentiated carcinoma, 6 cases, unclassified, 14 cases, and without biopsy 10 cases. At the end of March, 1942, 45 of the 68 patients were known to be dead, 8 were living, and 15 could not be traced. Ten of the entire group were considered favorable for surgical treatment. Of these, 3 were living when last heard from, but their present status is unknown. During the same period, 47 patients were selected for irradiation. Of these, 8 were living on April 1, 1942, 2 were free from evidence of disease, 4 were symptomatically improved, and 2 were in the terminal stage of the disease. The remaining 11 patients received no special treatment. The average duration of life for the 45 patients known to be dead, from the time diagnosis was established until death, whether they received special treatment or not, was four and a half months. For the 8 known to be living, the average lapse of time since the diagnosis was established is five and a third months.

The effectiveness of irradiation as a palliative measure in selected cases is difficult to express in figures, and can be shown best by the following two cases.

*Presented at the annual meeting of the Massachusetts Medical Society on May 27, 1942.

†From the Department of Radiology, Massachusetts General Hospital.
Read at Massachusetts General Hospital.

CASE 1. A 63-year-old man was admitted to the hospital on July 24, 1941, with a story of having been ill for 9 months. The illness had started with "pneumonia." The patient had lost 50 pounds in weight, and had a productive cough, which was severe, particularly at night. He complained of pain in the right shoulder, and difficulty in breathing when lying down.

Examination on admission showed cyanosis, without evidence of dilatation of the superficial veins; the breath sounds were slightly diminished over the entire chest, and the whispered voice was not transmitted. Dullness to percussion and tactile fremitus were absent. X-ray examination showed a lobulated mass in the region of the right hilum, with diminished aeration throughout the entire right lung field. These findings were considered to be consistent with primary bronchogenic carcinoma. The x-ray diagnosis was confirmed by bronchoscopy, and a biopsy taken at this examination showed oat-cell carcinoma.

X-ray therapy was advised, and the first treatment was given on August 5, 3 days after a definite diagnosis had been established. The treatment was given through two portals, one front and one back, centered over the mass; supervoltage x-rays were used. The patient received a total of 3000 r to the anterior and 2900 r to the posterior right chest. Treatments were given through a 12-by-12 cm. field in daily doses of 300 r. During the treatment, the patient developed a spiking temperature, which did not return to normal until 5 days after treatment was completed. In September, he received an additional 1500 r to each area. From that time on, improvement was continuous, and a second bronchoscopy with biopsy, done on December 12, 4 months after the treatment was begun, failed to show any evidence of disease. At the time of his last visit, April 22, 1942, the patient had no complaints, had gained considerable weight and was doing some work.

Comment. This patient had a very malignant, rapidly growing, radiosensitive tumor. He appeared for examination rather late in the course of the disease, but the diagnosis was made within 10 days, treatment was given promptly, and the immediate results were excellent.

CASE 2. A 64-year-old man was admitted to the hospital on June 10, 1941, complaining of cough and generalized weakness of 5 months' duration. The cough was productive of small amounts of blood-streaked sputum. The patient had a feeling of pressure in the left chest, some dyspnea and an intermittent wheeze, and had lost weight.

On examination, the chest appeared emphysematous, the trachea and heart being displaced to the left; the breath sounds were harsh on the left, but there were no rales or areas of dullness. X-ray examination showed collapse of the left upper lobe, with a marked shift of the trachea and mediastinum to the left. The cause of the obstruction was not clear. On June 16, bronchoscopic examination revealed a tumor at the orifice of the left-upper-lobe bronchus. The biopsy diagnosis was epidermoid carcinoma, Grade III.

Because of the patient's age and generally poor condition, surgery was not advised. He was not started on x-ray treatment until August 22, over a month after the diagnosis was made. The reason for the delay is not clear from the record. The treatment was given through two 10-by-10 cm. fields, one anterior and one posterior over the tumor. The daily dose was 300 r, and the total dose to each field 3000 r; supervoltage x-rays were used. Following the treatment, there was disappearance of symp-

toms, and an x-ray examination on December 3 showed re-expansion of the collapsed lobe and no visible tumor. A second bronchoscopic examination on December 5 showed no visible tumor; a biopsy was negative.

When last seen, on April 8, 1942, the patient was symptom free and looked well. X-ray examination, however, showed a small, rounded mass in the left 2nd interspace which may have been a recurrence.

Comment. This patient's life was made more comfortable and probably has been considerably prolonged by the treatment. Possibly, a better result could have been obtained if the delay between diagnosis and treatment had been avoided.

In both cases there is fairly definite evidence that it is possible to destroy the primary tumor with the treatment used.

DISCUSSION

Since the roentgenologic examination plays such a major part in the early diagnosis of cancer of the bronchus, I have attempted to group the cases according to their anatomic and histologic diagnosis in the hope that a better understanding of the basic pathological picture would improve the interpretation of the roentgenologic findings. Figure 1 is a schematic representation of the pathologic findings as demonstrated on the films. It is obvious that the roentgenologic appearance depends on the following factors: the location of the tumor, the type of tumor, the stage of the disease and the complications present.

The tumor may develop in one of the larger bronchi or in any of their more distal bifurcations, and its location determines whether it is seen as a central or peripheral shadow. It may grow outward into the lung substance, forming a more or less rounded, dense mass, with displacement of the adjoining bronchi away from the mass, or it may extend into the bronchial lumen, causing partial or complete obstruction of the bronchus. The latter type of tumor is more difficult to demonstrate roentgenologically, but it can often be seen as a mass within the bronchial lumen on films taken with the Bucky-Potter diaphragm, with the planograph, or after the injection of lipiodol.

More frequently, the presence of a tumor is suspected from the obstruction that it causes. The roentgenologic sign of bronchial obstruction varies with the degree of obstruction. When obstruction is partial, air enters the affected lung area with each inspiration, but its exit is prevented by the decrease in the bronchial lumen during expiration, and the area beyond the bronchial plug appears on the screen or film as a localized area of emphysema. If the obstruction is in a major bronchus, a shift of the heart and mediastinum away from the affected bronchus

occurs during expiration. This sign of bronchial obstruction is best demonstrated on films taken at the end of the expiratory phase, and may be

A persistent, low grade pneumonitis may develop, appearing on the film as an area of homogeneous density corresponding in size and

FIGURE 1

A—Early apical tumor arising in a terminal bronchus often called Pancoast tumor—early symptoms—pain in the shoulder and sometimes Horner syndrome diagnosis made by aspiration biopsy B—Extraluminal bronchial tumor—symptoms and physical signs absent, diagnosis made by surgical exploration C—Intraluminal bronchial tumor causing obstruction and obstruction pneumonitis—symptoms—cough and sometimes bloody sputum diagnosis made by bronchoscopy D—Intraluminal tumor causing partial obstruction, ball valve type with localized emphysema—symptoms—same as in C diagnosis made by bronchoscopy E—Intramural tumor causing complete obstruction with collapse of the right upper lobe—symptoms—cough, blood spitting and sometimes dyspnea diagnosis made by bronchoscopy F—Rapidly growing tumor with extension to regional nodes with or without signs of bronchial obstruction—symptoms—same as in E diagnosis made by bronchoscopy

entirely missed when the examination is confined to films taken at full inspiration. As the lesion increases in size, and obstruction of the bronchus becomes more complete, one of the three following changes may take place in the area of lung supplied by the plugged bronchus

shape to the portion of the lung supplied by the involved bronchus

The part of the lung beyond the plug may become water logged (the so called 'drowned lung'), with subsequent infection, necrosis and abscess formation. In such cases, the shadow

seen on the film may have a somewhat mottled appearance, and cavities containing fluid levels may be demonstrated.

There may be a more or less complete col-

like or triangular areas of increased density replacing a lobe or a portion of a lobe. The lung adjoining the diseased area is unusually bright, owing to compensatory emphysema. The

FIGURE 2.

A—Advanced apical tumor with extension to pleura and regional nodes; symptoms—cough, pain in shoulder, radiating down arm, and, usually, Horner syndrome; sometimes, signs of phrenic-nerve paralysis. B and C—Large extraluminal tumor with necrotic center, involvement of the pleura, fluid in the pleural space and foul and often bloody sputum; pieces of tumor may be coughed up; may be mistaken for lung abscess. D—Intraluminal tumor with complete block and drowned or necrotic lung, which may contain small cavities; sputum may be foul; fever and other signs of infection present. E—Small peripheral tumor with direct extension to the pleura; pleuritic pain and small amount of fluid in the pleural space; diagnosis made by thoracoscopy.

lapse of the lung distal to the plug. The roentgenologic appearance varies according to the size of the area involved, the completeness of the collapse and the length of time it is present. These collapsed areas are usually seen best in the lateral view of the chest, when they appear as band-

interlobar septums, when visible, are displaced toward the collapsed area. When an entire lobe is involved and the process is not of too long standing, there is a shift of the heart and mediastinum toward the affected side during inspiration.

Removal of the plug may result in a return of the lung to its normal appearance. It should not be forgotten that the commonest cause of bronchial obstruction is not carcinoma, or that a benign adenoma may be confused with a malignant tumor.

The histologic characteristics of the tumor play a part in determining the roentgenologic appearance, but a less significant one than the location of the tumor. The oat-cell and undifferentiated carcinomas rarely if ever produce rounded, sharply defined masses outside the bronchial lumen, although they not infrequently involve the lung, being seen as poorly defined, irregular shadows extending outward from the affected bronchus.

When the disease is far advanced, after it has extended beyond the regional lymph nodes, or when there is widespread infection with fluid in the pleural space, the picture is dominated by these secondary manifestations, and roentgenologic examination may be of little value in determining the underlying cause. At this point, reliance should be placed on other methods of diagnosis.

A knowledge of the usual distribution of the metastases in carcinoma of the bronchus is of considerable advantage in the interpretation of the roentgenologic findings and of the clinical symptoms. Enlargement of the peribronchial and peritracheal lymph nodes occurs relatively early, and should always be looked for. This enlargement is of diagnostic value and has a direct bearing on the question of operability. Extension to the pleural surfaces seems to occur more frequently. A tumor arises in a minor bronchus, is situated near one of the interlobar veins, and with massive involvement of the lymph nodes, the phrenic nerve may be involved, and roentgenologic examination will show in addition to the enlarged nodes, a paralysis of the diaphragm on the affected side. When the pleura is involved, there is usually evidence of fluid in the pleural space, and nodules on the pleural surface can sometimes be demonstrated after artificial pneumothorax. Clinically, these patients complain of pleural pain, and if the process is at the apex they may have a *Horner syndrome*. Metastasis to bone is not uncommon, but the roentgenologic appearance does not differ materially from that seen in other metastatic bone tumors. Metastasis to the brain, liver, adrenal glands or mesenteric lymph nodes occurs very often, and may give rather characteristic symptoms, although the masses are not usually demonstrated on the film. When the disease is complicated by an extensive infectious process, the roentgenologic appearance is that of infection, and the underlying tumor may

be overlooked. The differentiation of these tumors from other obstructing lesions of the bronchi, from pulmonary metastasis of tumors arising in other parts of the body and from benign tumors of the bronchi is largely dependent on the clinical history and the bronchoscopic examination. The worth of roentgenologic examination is in the demonstration of a lesion consistent with carcinoma of the bronchus to the end that other more complicated diagnostic methods may be undertaken.

Before these patients are subjected to irradiation, the diagnosis should be definitely established, preferably by biopsy. Benign tumors should be ruled out, since the surgical results in this group are excellent and only harm can result from irradiation. No case in which there is a reasonable chance of complete surgical removal should receive roentgenologic treatment, and cases in which extensive metastases have already occurred, or in which massive infection is present, are probably better treated by other means.

The cases in which benefit from irradiation may be expected are those with oat-cell or undifferentiated carcinoma without definite evidence of metastasis beyond the regional lymph nodes. In this rather large group, the evidence of benefit from irradiation is of course, not conclusive.

imm-
advantage
of treatment

In presentation, I have seemed to place emphasis on the use of the roentgen ray in the diagnosis and treatment of bronchogenic carcinoma, it is not because I do not appreciate that medicine and surgery play the major part in the problem, but because the roentgen ray is the part in which I am most interested and because it has received less attention. The medical and surgical aspects have been covered thoroughly by other physicians at the Massachusetts General Hospital, and I am very much indebted to them for permission to use their material.

THE PLACE OF GASTRODUODENOSTOMY IN THE SURGERY OF DUODENAL ULCER*

HOWARD M. CLUTE, M.D.,† AND JOHN S. SPRAGUE, M.D.‡

BOSTON

FOR some years, the consensus has been that simple duodenal ulcer is primarily a medical problem, and it is well known that 80 to 90 per cent of duodenal ulcers can be satisfactorily managed by medical treatment. When complications occur in the course of a duodenal ulcer, however, surgery is necessary. The chief complications of duodenal ulcer that may require surgery are acute perforation, hemorrhage, pyloric obstruction and a failure of medical measures to give satisfactory relief of symptoms.

In past years, the majority of surgeons employed a short-circuiting operation for duodenal ulcers that had developed any of the above complications. In many cases, lasting relief was obtained by this procedure. As time went on, however, it became increasingly evident that the frequency of gastrojejunal ulceration after posterior gastroenterostomy was great and that this lesion was more trying than the original ulcer. Surgical opinion turned more and more to subtotal gastrectomy as the procedure of choice in complicated ulcers. It is now generally believed that, when possible, a resection of two-thirds or more of the stomach, which must include the pylorus, is best in the treatment of duodenal ulcers with hemorrhage or intractable to medical treatment. We are in complete accord with this opinion. In our clinic, patients with duodenal ulcers who have failed to gain relief from careful medical treatment are subjected to radical subtotal gastrectomy; patients who have had repeated hemorrhages from the

duodenal ulcer are likewise subjected to gastric resection when operative interference is deemed necessary.

In 1938, we§ described the technic and reported the results in a small group of cases of duodenal ulcer in which a gastroduodenostomy, instead of a posterior gastroenterostomy, had been performed. The results were uniformly good, but we realized that sufficient time had not elapsed after the operation to make the report especially significant.

The 15 cases reported in 1938 and 11 more cases since then have been followed to date. It is our opinion that we are beginning to have some definite information regarding the dangers and complications that may follow gastroduodenostomy and the benefits that one may anticipate from this procedure. From these facts, the indications for gastroduodenostomy in certain duodenal ulcers may be decided.

In our experience, pyloric stenosis following a long-standing duodenal ulcer is completely and permanently relieved by gastroduodenostomy. For many years, it has been known that the best results of posterior gastroenterostomy have followed its use as a short-circuiting procedure in duodenal ulcers that had produced a fibrous stenosis of the pylorus. The question arises, Why should one use gastroduodenostomy in these cases instead of the time-tried posterior gastroenterostomy? We prefer gastroduodenostomy because it is more easily and simply performed and has less immediate postoperative complications. Furthermore, in our cases, there has not been, as yet, even a suggestion of later jejunal ulceration. Finally, it

§Clute, H. M., and Sprague, J. S. Gastroduodenostomy for certain duodenal ulcers. *J. A. M. A.* 111:909-914, 1938.

has long seemed to us that normal physiology was more closely approximated when the acid gastric contents were emptied into the second part of the duodenum than when they were poured into the jejunum

In the previous paper, we reported 7 patients with pyloric stenosis treated by gastroduodenostomy. We have recently reexamined all these patients. They are without exception perfectly well, so far as their digestive apparatus is concerned. They eat as they wish, and have no indigestion or distress. Since our last report, we have done eleven more gastroduodenostomies for pyloric stenosis, all these patients are well, with no digestive troubles. Thus, 16 patients with obstructing duodenal ulcers have been treated with gastroduodenostomies and followed from a few months to seven years with such satisfactory results that we are deeply impressed. We realize that this is a small group of patients and that half of them have been followed less than five years. However, this carefully followed group does give a definite suggestion that gastroduodenostomy may be preferable to other short circuiting operations in obstructing duodenal ulcers. We are completely satisfied that the procedure is preferable to subtotal gastric resection for these patients, who are usually old and whose body chemistry is seriously altered by their pyloric stenosis.

We have used gastroduodenostomy in the surgical management of two gastrojejunal ulcers that followed posterior gastroenterostomy. One of these patients was fifty five and the other fifty nine years of age. Both entered the hospital with active serious hemorrhage from the gastrojejunal ulceration and presented a very serious surgical problem. We agree that the ideal procedure in the management of gastrojejunal ulcer is removal of the loop of jejunum and its stoma from the stomach, closure of the jejunum by suture of the orifice or end to end anastomosis, resection of the stomach and performance of an anterior or posterior Polya type of anastomosis.

The third part of the procedure, in our experience, may be more than the patient can safely bear, since this resection must follow the removal of the jejunum from the stomach and its suture. We know that it is dangerous to remove the jejunum, close it and close the gastric defect, and do nothing to the duodenum, even though the duodenal ulcer seems to be quiescent. Reactivation of the duodenal ulcer, with hemorrhage, perforation or obstruction, occurs too frequently under these conditions. In these 2 patients, treated seven and six years ago, a gastroduodenostomy was quickly and readily done after the bleeding gastrojejunal ulcer was excised and the stomach and jejunum closed. Both patients

have been followed to date and are quite free from digestive troubles. We believe that, under circumstances such as these, gastroduodenostomy rather than partial gastrectomy may be a lifesaving procedure. We shall have no hesitation in carrying out this operation in future patients with gastrojejunal ulcers who are poor risks.

We do not consider gastroduodenostomy the method of choice for the surgical management of a bleeding duodenal ulcer, in which resection of the ulcer and a radical resection of the stomach should be done, if any surgery is undertaken. We did a gastroduodenostomy for a bleeding duodenal ulcer in 1935. The patient died a few hours after operation. This is the only death we have ever had following gastroduodenostomy. In 1936, we did a second gastroduodenostomy for a duodenal ulcer with repeated hemorrhages. This patient is well, six years later, and has no digestive trouble.

We do not believe that gastroduodenostomy is a procedure of choice in the surgery of gastric ulcer, although we have twice used it in conjunction with local excision of the lesion. Both patients are now well, one seven years and the other four years after operation. In each of these cases, the ulcer was very high on the lesser curvature of the stomach, and its removal would have necessitated almost a total gastric resection. One of the patients has had several trying bouts with recurrent gastric ulcer since operation, but since he is now well he will not consider reoperation. The other patient has remained well. It is perhaps true that in certain very high gastric ulcers, local excision of the ulcer and gastroduodenostomy will prove satisfactory, but, in general, a radical subtotal gastrectomy is preferred in these cases.

Certain duodenal ulcers cause distress and disability in spite of long-continued and careful medical treatment. These patients, in our opinion, should have radical subtotal gastric resections and neither posterior gastroenterostomy nor gastroduodenostomy. In such patients, high gastric acidity is common preoperatively and gastrojejunal ulceration postoperatively, unless the gastric antrum and most of the acid secreting gastric glands are removed surgically.

We have done gastroduodenostomies in 4 patients because of the failure of medical treatment. One of these patients—and the only case in our series—cannot be traced. Two have remained well and have no digestive troubles four and five years, respectively, after operation. The fourth patient has about as much indigestion now as she did before operation, and she represents the only known failure in the series. Since operation, she has gone through a divorce and has also lost her mother. Her diet is entirely unsatisfactory. We are

at present following her in the Gastro-Intestinal Out Patient Department with the hope that a proper diet will give relief. There is no evidence of a stomial ulcer in this case. We have every reason to believe that our own judgment was at fault in selecting the surgical procedure.

SUMMARY

Twenty-six gastroduodenostomies have been performed for the complications of duodenal ulcer, with one death. One case has been lost, but the remaining 24 have been followed to date.

In 16 cases of organic pyloric stenosis, the results have been so entirely satisfactory that we have been greatly impressed with the value of the operation in this condition.

Two patients with bleeding gastrojejunal ulcers were treated by resection of the jejunal ulcer and closure of the jejunum and stomach; a gastroduodenostomy instead of a gastric resection was done because of their condition. Both patients have remained well for many years. Under these

circumstances, we believe gastroduodenostomy may frequently be a lifesaving procedure.

We do not recommend gastroduodenostomy for the treatment of serious hemorrhage from duodenal ulcer or when medical treatment has failed; subtotal gastric resection is the operation of choice for these conditions.

Only rarely is gastroduodenostomy, in combination with local excision of an ulcer high on the lesser curvature of the stomach, employed. In some cases, however, this conservative procedure may well be preferable to a total or nearly total gastrectomy for these lesions.

In our experience, gastroduodenostomy is even more easily done than posterior gastroenterostomy, and certainly the patients have a smoother post-operative course. No gastrojejunal ulceration has followed gastroduodenostomy in our experience. This seems logical, since in gastroduodenostomy the acid gastric secretion empties into the duodenum, which is prepared for it, rather than into the jejunum, which is not.

CLINICAL NOTE

A DEVICE FOR THE INTERNAL FIXATION OF BONE

LYMAN SMITH, M.D.*

BARRINGTON, ILLINOIS

INTERNAL fixation of bone is rapidly coming into more general use in the treatment of fractures. The surgical and physiologic problems have been fairly well solved. The mechanical aspects of this engineering problem, however, are of equal importance and have recently been receiving an increasing measure of attention. In 1938, Hawley and Padula¹ introduced an angle plate that does not bend; Murray² advocated the use of a transfixion screw crossing the fracture site in conjunction with the usual plate. Lyon, Cochran and Smith³ tested the holding power of various types of screws used in bone and determined the correct size of drill for each. All this work was directed toward increasing, as much as possible, the efficiency of the internal immobilization. It is the purpose of this paper to present a device that is mechanically more efficient than the screws in present-day use.

The device, illustrated in Figure 1, is a screw-type expansion sleeve.[†] It consists of two parts:

*Formerly, resident, Bone and Joint Service, Boston City Hospital.

[†]The development of this device is due, in large part, to the generous co-operation of the Illinois Tool Company, Chicago.

a small screw threaded about half its length, and a sleeve member into which the screw is seated. The sleeve is slit into four sections, which are so tapered that, when the leading point of the screw engages them, they are forced open and thus form a wedge.

Up to the present time, this device has been used only in cancellous bone, to which it is applied in the following manner: a 6/32-inch hole is drilled to the desired depth, and an expansion sleeve of the proper length is then selected and inserted into the drill hole; the head of the sleeve is grasped with a forceps to prevent rotation, and the screw member is then seated with a small screw driver.

Delay in obtaining machine tools has prevented its use in cortical bone. Obviously, the sleeve sections of the device cannot expand against such hard material as cortical bone; instead, therefore, one must use a tool that will enter a drill hole on the exposed surface of a bone and ream out a wider bore below the surface, equaling the diameter of the expansion sleeve. One such instrument has been designed and used experimentally, but is not yet perfected.

The mechanical principle underlying the expansion sleeve is not new, since similar fasteners are used in cement and brickwork.

The holding power of a nail or screw in soft cancellous bone is not great. In experimental animals, however, these sleeves averaged 40 per cent more holding power in cancellous bone than

coarse deep threaded screw. This added fixation is of advantage in allowing early motion after

the screw, whereas the opposite is true of the expansion sleeve. For this reason, absorption of

FIGURE 1 Screw Type Expansion Sleeve

A—Expansion sleeve closed, screw not seated B—Expansion sleeve opened, screw seated, forcing sleeve sections open C—Distal end closed D—Distal end opened

reduction, which is desirable in fractures around joints.

Venable, Stuck and Beach⁴ have proved that resorption of bone around screws made of alloys, other than vitallium, is caused by electrolytic irritation. The stresses produced about a screw, however, also result in absorption of bone and subsequent loosening. Figure 2 illustrates the stresses around a screw and around an expansion sleeve, both used to fasten together two pieces of Marblette, a phenol resin plastic that has a high photoelastic property to show strain effects produced by concentration of pressure. The magnitude of these stresses is dependent on the number of dark and light lines concentrated at any one point or area. The photograph shows that the stresses are very prominent and concentrated about

FIGURE 2 Lines of Stress about a Screw and an Expansion Sleeve

bone about the expansion sleeve is slower and less marked than that about a screw.

Removal of an expansion sleeve weeks after insertion, when it had served its purpose, might be thought difficult because of the formation of

FIGURE 3. *Expansion Sleeve Six Weeks after Insertion in a Dog's Femur.*

callus between the screw member and the expanded sleeve sections. This has not proved to be so. Figure 3 shows an expansion sleeve

buried for six weeks in the greater trochanter of a dog's femur. There was no absorption of bone about the sleeve, which, on examination, was found to be seated firmly. After the screw member had been turned out, the sleeve was easily extracted. Expansion sleeves in place as long as ten weeks have likewise been easily removed.

Since accurate machining of this device is necessary, it cannot be made from such a hard alloy as vitallium, which must be cast. However, the new S-Mo (Enduro) stainless steel has been found to be practically as inert in the tissues as vitallium. If the expansion sleeve were manufactured from stainless steel in large numbers, its cost would probably not exceed that of a vitallium screw.

SUMMARY

A new device for the internal fixation of bone is presented. It is simple to apply, exhibits greater holding power than a screw and creates fewer lines of stress in the bone about it. It has no apparent disadvantages.

MEDICAL PROGRESS

CARCINOMA OF THE PROSTATE

WILLIAM C. QUINBY, M.D.*

BOSTON

ANY consideration of the subject of carcinoma of the prostate must emphasize once again the frequency of its occurrence in all men past the age of fifty years. From the clinical viewpoint, it has long been recognized that in about 20 per cent. of all male patients of this age who have symptoms of prostatism, these symptoms are found to be due to a prostatic carcinoma. More recent inquiry into the incidence of prostatic carcinoma comes from routine post-mortem examination by the pathologist, by which additional cases of cancer are demonstrated in many patients dying from various other conditions who showed no evidence of prostatic carcinoma during life. Thus, Moore¹

finds carcinoma of the prostate in 17 per cent of all men over fifty years, and this incidence increases steadily with age, until it reaches 29 per cent in patients who are in the ninth decade. The disease probably originates in cells that have previously undergone atrophy of a senile type. A more recent study of this subject by Kahler² at the Mayo Clinic has given similar figures. His observations were derived from 195 cases. In 72, the diagnosis was made ante mortem; in 69, the carcinoma was discovered only at autopsy; and in 54, it was found only by a more detailed study of sections in cases that had previously been considered benign both clinically and pathologically. The clinical diagnosis was made by palpation in 23 cases, by palpation and biopsy in 30 cases, and by the presence of characteristic distant metastases in 19 cases. The average age of these patients

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress Annual*, Vol. III, 1942 (Springfield, Illinois: Charles C. Thomas Company, 1942 \$5.00).

*Clinical professor of genitourinary surgery, emeritus; urological consultant, Peter Bent Brigham Hospital

was sixty-five years, and the total incidence of carcinoma 17.3 per cent. Of tumors recognized either clinically or grossly at necropsy, 54 per cent had produced metastases. So far as the point of origin of the neoplasm in the prostate is concerned the lateral and posterior lobes were most frequently involved. The growth never arose in the median lobe. In several cases, its origin appeared to be "multicentric." The type of tumor was squamous cell in 3 per cent of the cases and adenocarcinoma in the others, whose malignancy was classified as Grades I and II in 69 per cent. This, of course, reflects the clinical experience that prostatic cancer is a slowly growing type of tumor on the whole, spreading most frequently by metastases, rather than by invasion of contiguous structures.

Regarding the manner of extension of the original growth, the perineural lymphatics were found to contain cells in all cases in which the tumor was of the more malignant types—Grades III and IV—and in 91 per cent of all tumors investigated, regardless of type. Therefore, if one considers this evidence conclusive, one must agree with Kahler that "it makes very questionable the possibility of operative cure." Moore² also called attention to this frequent invasion of the perineural lymphatics, even in early stages of the disease. Further investigation into the mode of spread of carcinoma of the prostate has been carried out by Warren and his co-workers.³ Although transport by means of the blood stream is undoubted, they believe that the perineural lymphatics offer the tumor an additional way of access to bone and that this fact accounts for the marked frequency with which the bony pelvis and lower vertebrae become involved, as compared with regions more distant from the tumor.

Such observations as these, combined with the insidious progress of the growth that makes early clinical recognition of its presence infrequent, have led to a rather widespread attitude of defeatism concerning the operative treatment of prostatic carcinoma, which is often unjustified. It is to be remembered always that the pathologist can describe with accuracy only what he sees in the individual microscopic slide. Beyond this, conclusions regarding cause and effect may easily be fallacious. It is wrong, for example, to assume that a tumor cell lying apparently free in a tissue space surrounding a nerve is undergoing transport in a direction away from its point of origin. Furthermore, the term "perineural lymphatic" is not at all accurate, for the accepted connotation of "lymphatic" is that of a tubular structure walled by endothelial cells, a part of the general lymphatic apparatus of the body. The implication is that there is a progression of the fluid or lymph con-

tained in such a lymphatic in the direction of the more central areas of the body, the current being similar to, although slower than, that in the capillaries leading to veins. The areas about the very numerous sympathetic nerve fibrils with which the prostate is supplied are really only tissue spaces—lymph spaces, possibly, but certainly not true lymphatics. That a cancer cell lying in such a space about a nerve fibril will be viable on transportation to some distant point of the body, or is even being so transported, is not proved by any evidence at hand. Metastasis by way of the blood stream, especially by the veins, is of course acknowledged, but that these cells in proximity to nerve fibrils play a significant part in the spread of the neoplasm is yet to be demonstrated. Certainly, the clinical evidence afforded by the recorded cures after total prostatectomy, together with the well-known slow progress of prostatic carcinoma in general, suggests strongly that this perineural invasion is of little prognostic significance. The observations of Warren and his associates were derived from autopsy and thus represent only the terminal picture of the malignant process.

A valuable aid in the study of prostatic carcinoma has been the result of examination into its relation to the enzyme phosphatase present in tissues and appearing also in the serum of the blood. This enzyme, acting as a catalyst, has the power of liberating phosphate ions from phosphoric acid esters. The amount so liberated depends on the reaction of the solution in which it takes place. Thus, the optimum pH for the alkaline phosphatase is 8.6, whereas that for the acid phosphatase is 4.8 to 5.0. The reaction is expressed in units per 100 cc. of blood serum.

Following the demonstration on phosphatase by Bodansky⁴ and that by Kutscher and Wolbergs,⁵ which showed that prostatic tissue contains a large amount of acid phosphatase and but little alkaline phosphatase, the Gutmans⁶ have studied this subject extensively. They found that the prostate in the newborn contained 4.5 units per gram of tissue; that of a boy of four years, 1.5 units; and that of a boy of thirteen years, 73 units; whereas the prostate of the adult man showed much greater phosphate activity, varying from 522 to 2284 units. Evidently, therefore, the content of the prostate in phosphatase bears a definite relation to its maturity, increasing markedly after puberty and represents a secondary sex characteristic of a chemical nature. In the blood serum of normal persons, the amount of acid phosphatase activity was found to be from 0.5 to 2.5 units per 100 cc. In patients with bone metastases from prostatic carcinoma,

however, a very marked increase in the amount of acid phosphatase in the blood serum takes place, whereas in the serum of patients with prostatic carcinoma but no metastases, the phosphatase readings are normal.

Gomori⁷ has devised special staining methods by which it is possible to demonstrate phosphatase in tissues. Prostates containing carcinoma when so stained show an abundant black deposit, owing to the large amount of phosphatase present.

The important studies on the relation of the prostate to the various endocrines, and especially to the sex hormones, undertaken by Huggins and his collaborators⁸⁻¹³ at the University of Chicago have had an especially significant result in the field of therapy of carcinoma of this gland. An operation was devised by which the prostate of dogs was separated from the urinary tract so that prostatic activity could be studied over long periods in response to various conditions or injections. Determination of prostatic activity was made after the collection for one hour of the secretion caused by an injection of 6 mg. of pilocarpine. Castration of such dogs was followed by marked and increasing reduction and eventual cessation of the prostatic secretion in from seven to twenty-three days. After this, the secretion could be re-established by the injection of testosterone. This depression of prostatic secretion after removal of the testes, well recognized for years in both man and animals, therefore depends on the reduction of the male sex hormones, the androgens, of whose greatest amount the testis is the origin. The concept then followed that prostatic carcinoma, being composed of epithelial cells of a mature type, might be responsive to a depression of the androgenic hormones in the organism, in common with all other types of adult prostatic epithelium. Using the phosphatase estimation as a method of objective proof of the concept, these workers found that androgen injection caused a marked rise of acid phosphatase in patients with prostatic carcinoma and that castration or estrogen (female sex hormone) injection produced a sharp decrease in the activity of the phosphatase.

Twenty-one patients with advanced prostatic cancer were castrated, and the clinical effects observed during twenty months. Four of the men died, and in 2 the clinical results were reported as unsatisfactory. The authors further state:

In those patients who were improved the more objective clinical evidence of tumor regression consisted of increased appetite and a progressive gain in weight; improvement in red cell and hemoglobin values; decrease in pain and objective neurological symptoms (2 patients who had compression of the cauda equina with a complete block of the subarachnoid space had a restoration of the circulation of cerebrospinal fluid and resolution of the paralytic and anesthetic changes

following castration); decrease in the size of the primary tumor on rectal palpation and at cystoscopic examination; stabilization or regression of bony metastases in roentgenograms; and a decrease in the size of palpable lymph nodes which were the site of metastatic cancer. It was our opinion that complete regression of the tumor had not taken place, although the depression of the tumor activity with resulting improvement of the patient in some cases was considerable. In about 20 per cent of the cases the results were unsatisfactory. Further observations found that the administration of stilbestrol reduced still further the level of the acid phosphatase below that reached after castration. Estrogen is therefore found to supplement the action of lowering the androgens of the body brought about by castration.

Following this very important report made at the meeting of the American Urological Association in May, 1941, many patients with prostatic carcinoma have been subjected to orchidectomy, with results that in some cases have been quite phenomenal. The most striking benefit was usually the relief of conditions caused by the metastases; in several well-authenticated cases, the patient, partially paralyzed by pressure on the spinal cord and nerve roots, was freed from pain and again able to walk. That orchidectomy does not result in a total resolution of the cancer in the prostate itself seems to be generally acknowledged. Nevertheless, there is no doubt that this procedure relieves many of the most prostrating symptoms of the sufferers.

Other methods of reducing the androgens in the body are exposure of the testes to the destructive action of the x-ray and the use of an estrogen, such as diethylstilbestrol. Munger¹⁴ reports a series of cases of prostatic carcinoma treated by resection followed by irradiation of the testes. He believes that such x-ray treatment has given some added benefit, but his results do not seem very convincing. Herrold¹⁵ reports 12 patients with cancer of the prostate to whom diethylstilbestrol was given. A consistent result was seen in the relief of pain. Also, the patients showed an improvement in general condition and, in some cases, a gain in weight. Rectal palpation in one patient who had taken the drug to the amount of 350 mg. during a period of five and a half months showed a diminution in the size of the growth of about 50 per cent and a diminution in its hardness. Pain in the breasts, with some increase in size (gynecomastia), was the only untoward result of the administration of the drug in daily doses of 3 mg. The effects following testicular irradiation or diethylstilbestrol, however, in no case are reported to be so outstanding as those seen after orchidectomy.

It is of interest, in view of the newer knowledge of the sex hormones and their effect on castration, to consult the early opinions concerning this procedure as a method of treating the enlarged and

obstructing prostate. Before the American Surgical Society, in 1893, White¹⁶ read a paper advocating orchidectomy for the hypertrophied prostate after having demonstrated that this operation causes atrophy of the prostate in dogs. Three years later, Cabot¹⁷ presented to the same society an analysis of the clinical results of this operation in man. No distinction was made between a benign and a malignant hyperplasia of the prostate. The results on the whole were poor, although an occasional case was found in which the improvement in the patient's condition and ability to empty the bladder was marked. It was probably the malignant prostate in which a favorable reaction to operation was obtained.

Those who advocate total removal of the gland whenever possible are increasing steadily. There is no longer any doubt of the excellent results of such removal in cases in which the diagnosis has been made sufficiently early. The recent papers of Colston¹⁸ and of Lowsley and Kilgore¹⁹ bear witness to this fact. For patients in whom the carcinomatous invasion is too extensive to permit a total prostatectomy, resection of the obstructing portions by way of the urethra is of inestimable value, as brought out in the paper of Wishard, Hamer and Mertz.²⁰ The use of radium either in the form of the salt or as emanations in "seeds," rather general a few years ago, today finds fewer advocates.

* * *

Recent advances in the knowledge of the biologic characteristics of carcinoma of the prostate have already resulted in markedly increasing ability to relieve the symptoms of sufferers from this disease. A defeatist attitude today is entirely unjustified.

Continued emphasis must be placed on the early detection of the carcinomatous prostate by rectal examination of men fifty years of age and older as an important part of an annual physical examination. Because of the insidious progress of this disease, in no other way will the number of cases amenable to total removal of the gland be increased, and to date this is the only method of cure.

A more general use of the biopsy in every suspected case is strongly advised, even though at times this necessitates an exposure of the prostate through the perineum.

Patients with prostatic carcinoma should be studied at frequent intervals, both before and after operation, by estimation of the phosphatase activity of the blood serum and by x-ray study of the spine and pelvis as indices of their condition.

The growth of prostatic carcinoma is retarded by a reduction of the amount of androgenic sub-

stances present in the body. Such a reduction is brought about primarily by castration, and secondarily, and to a much less degree, by the administration of one of the estrogens, preferably diethylstilbestrol.

A suggested course of treatment of patients with prostatic carcinoma is as follows: for patients with few or no urinary symptoms but with an amount of carcinomatous invasion too extensive to permit total prostatectomy, castration, followed by diethylstilbestrol is advised; for those with obstructive symptoms and a degree of malignant invasion too extensive for total prostatectomy, transurethral resection, combined with castration, is preferred; in patients for whom total prostatectomy can be done but who already have metastases, prostatectomy, followed at least by stilbestrol, and possibly by castration if the acid phosphatase remains high, should be performed; patients amenable to radical excision of the gland should have operation, followed by careful observation of the phosphatase readings, castration being reserved until high values of this enzyme indicate its need.

TRACY B. MALLORY, M.D., *Editor*

CASE 28401

PRESENTATION OF CASE

First admission. A six-month-old male infant was admitted to the hospital because of cough, vomiting and a shrill cry.

Three weeks prior to entry, the child began to vomit his feedings immediately after ingestion. During this time, he developed a cough productive of small amounts of sputum. This did not occur in paroxysms and was not similar to the cough of whooping cough. However, vomiting often occurred after coughing. The physician did not find the temperature elevated, but the child seemed to perspire, particularly about the head. The symptoms were unaffected by variation in the feeding formula. During the three days before admission, the child vomited everything consumed, and the vomiting was termed "almost projectile." He became quite constipated and lost 2 pounds.

The family history was irrelevant. Two siblings, aged four and two years respectively, were well.

Born at term after a normal spontaneous delivery, the patient was declared "a small baby," but was vigorous and quite normal. The development was normal, and the diet adequate.

Physical examination revealed a pale, poorly nourished, slightly dehydrated, weak, flabby infant with a high-pitched, feeble cry. The throat was slightly congested and filled with mucus. The heart and lungs were normal. The abdomen was soft and scaphoid. The liver edge was felt 1 or 2 cm. below the costal margin. Neurologic examination was negative.

The temperature was 99.2°F., the pulse 150, and the respirations 30.

Examination of the blood revealed a red-cell count of 2,350,000 with a hemoglobin of 40 per cent, and a white-cell count of 7400 with 43 per cent polymorphonuclears and 57 per cent lymphocytes; the hematocrit was 23 per cent. The blood Hinton reaction was negative. Examination of the urine was negative. X-ray examination of the long bones, skull and chest was negative. The tuberculin test was negative.

The child was treated with physiologic saline infusions, blood transfusions and a gradually increased formula. The anemia cleared. The patient was discharged after seventeen days, apparently improved.

Second admission (eight days later). The mother stated that on the day of discharge from the hospital she noticed that the patient's fingers and toes were blue. On the second day after discharge, he began to vomit after feedings, although the hospital formula was followed. At times, a refeeding was not vomited, and water could be tolerated. The patient lost interest in his toys, lay quietly and fussed when picked up. A week later, he was found breathing with difficulty, and the fingers were blue. This became progressively worse, and a day later, he was readmitted to the hospital. He was said to have gained 12 ounces since discharge.

Physical examination revealed a pale, fretful, slightly dehydrated infant, who showed little interest in his surroundings and who cried when moved. The face and nail beds of the fingers and toes were blue. The fontanels were soft and were not sunken. The throat was moderately congested and filled with mucus.

Examination of the heart revealed only a tic-tac rhythm. The lungs seemed clear anteriorly, but showers of fine rales were heard in both upper lobes posteriorly and the chest seemed dull to flat in these areas. The abdomen was somewhat protuberant and tympanitic, and the umbilicus protruded. The liver edge was felt 3 cm. below the costal margin. The spleen was not felt.

The temperature was 102°F., the pulse 160, and the respirations 60 to 80.

Examination of the blood revealed a red-cell count of 4,000,000 with a hemoglobin of 87 per cent, and a white-cell count of 51,000 with 55 per cent polymorphonuclears. The following day, the white-cell count was 18,400 with 79 per cent polymorphonuclears. There was a marked anisocytosis, and many normoblasts were present on the blood smears. There was no sickling of the red cells. In the fragility test, no hemolysis occurred at 0.50 per cent, and at 0.25 per cent there was complete hemolysis. The carbon dioxide combining power was 15.7 milliequiv. per liter, and the nonprotein nitrogen was 20 mg. per 100 cc. The throat and stool cultures were negative for pathogenic organisms.

X-ray films of the bones showed no evidence of disease. The chest was described as being unusually large. The diaphragm was low in position. The size and shape of the heart showed no variation from the normal. No unusual masses were seen. The trachea and main bronchi were

clearly visible and appeared normal. In the fluoroscopic examination, the mediastinum appeared shifted to the left, but there was no respiratory change. The pulmonary markings were increased on both sides.

An electrocardiogram on the second day after admission showed a sinoauricular tachycardia, with a rate of 150 per minute. The PR interval was 0.12 second. There was a moderate right-axis deviation. Electrocardiographic studies done three and twelve days later revealed no significant change.

The patient was maintained quite well in an oxygen tent but became quite cyanotic when removed. On the eighth day, the red-cell count was 5,100,000 with 100 per cent hemoglobin, and the white-cell count was 11,200. He continued to gain weight. A marked pitting edema was noted on the eleventh hospital day, and clubbing of the fingers seemed to have developed. The liver became enlarged until the edge was felt at the crest of the ilium. On the day of death, the patient was removed from the oxygen tent for a bath. He became quite cyanotic and remained so after being returned to the oxygen tent, contrary to what had previously occurred. He died forty-five minutes after being returned to the tent.

DIFFERENTIAL DIAGNOSIS

DR. CONGER WILLIAMS: In summary, this infant entered the hospital for the first time because of an acute episode characterized by vomiting, cough and severe anemia from which he apparently recovered in seventeen days. A second episode starting eight days after discharge and characterized by vomiting, dyspnea, cyanosis, leukocytosis and fever ended in death thirteen days later, following the rapid development of what apparently was congestive heart failure, with rapid enlargement of the liver and pitting edema of the extremities. I think it is fair to say that the heart was probably involved, at least in the last few days. But it is necessary to find another explanation for the previous clinical findings.

On the first admission, there were several things of interest—first of all, the cough and vomiting. I gather that the vomiting soon cleared up following hospital admission, and knowing that vomiting can come from almost anything in an infant, I do not put much stress on that. I think the cough might have had some importance as possibly indicating upper respiratory infection. I shall go into that a little later.

One of the most interesting findings on the first admission was the rather severe anemia, and in an attempt to explain that, it is necessary to consider several possibilities. Was this a nutritional

anemia? The statement was made in the record that the diet was adequate, and yet physical examination on admission revealed a child who was rather poorly nourished. Did he have an infection that might possibly account for an anemia of this type? The white-cell count was normal. On admission, the temperature was only slightly elevated, and the smear was normal for a patient of his age. Two common causes of anemia in children on an infectious basis are syphilis and tuberculosis. I think we can rule them out by the negative blood Hinton reaction and the negative tuberculin test. The statement was also made that the throat was congested and filled with mucus. Of course, the mucus may have come from the nose or bronchi. The fact that the patient was coughing suggests that it may have come from the bronchi. Coughing was the commonest symptom and occurred fairly soon after the onset of his illness. I doubt if it would have been possible to make a definite diagnosis of bronchopneumonia or lobar pneumonia in this child, but he might possibly have had an upper respiratory infection, even a bronchitis.

Did the patient have pertussis? Whooping cough is very common at this age. He did not have the characteristic paroxysmal cough of pertussis, and yet it is well known that the clinical course is not necessarily classic in pertussis and may fall in a great many different patterns. The fact that the vomiting followed the cough is slightly suggestive. One thing that might be against the diagnosis of pertussis at this particular stage is the absence of a significantly high leukocytosis. It is well known that pertussis gives one of the highest leukocyte responses of any of the upper respiratory infections in children. Of course, it usually does not appear until the paroxysmal stage, but my understanding of it is that it should be present at the end of the second week at least. When the patient was admitted, he had been sick for three weeks.

Then the question arises, Did he have a primary anemia of infancy? One possibility to be considered is sickle-cell anemia. Nothing is said about the race; although sickle-cell anemia occurs almost always in Negroes, it may be seen in Italians.

Can you clear up that point, Dr. Mallory?

DR. TRACY B. MALLORY: The record simply states that the patient was born in Maine. The name suggests Scottish descent.

DR. WILLIAMS: I do not suppose that rules it out. A few features of the illness suggest sickle-cell anemia, which may occur at this age—six months—and apparently gives a picture similar to this, with a color index of almost 1.0, which this child had. Another thing consistent with sickle-cell anemia is the amount of hemolysis, par-

ticularly at the lower range. Hemolysis was not complete until 0.25 per cent. That is frequently seen in sickle-cell anemia. Also, one may see young red forms in the blood smear, which were present in this case. However, there are a few things against this diagnosis. One is the fact that reticulocytes were not mentioned. Ordinarily, there is a very high reticulocytosis with sickle-cell anemia. Another thing is the fact that, although the spleen is not ordinarily felt in adults, I understand that it is felt in children and infants with this disease. A spleen was not felt in this infant at any time. Another thing against it is the absence of icterus, which was not mentioned either clinically or by a laboratory test. Also, I should think that a complete clearing up of the anemia after the first episode would be against sickle-cell anemia. One thing known about the disease is the fact that these patients are susceptible to intercurrent infection. I think we have rather good evidence of infection in this infant. But I am inclined to discard the diagnosis of sickle-cell anemia, especially since we have nothing definite about the racial origin.

One of the other anemias seen in children is Cooley's anemia. There are several things against that. There is no note about the racial origin—Cooley's anemia usually occurs in Mediterraneans. The spleen is always greatly enlarged, and it was not felt in this case. Bone changes that are usually quite characteristic, especially changes in the skull, are not described. Cooley's anemia is likely to show icterus and a low color index, neither of which was found in this patient. The diagnosis of familial hemolytic jaundice can be thrown out, I think, on the absence of family history, splenic enlargement and jaundice. These patients also show decreased resistance to hemolysis by the fragility test, whereas this patient had increased resistance. Von Jasch's syndrome is another possibility. There is supposed to be high leukocytosis along with anemia, with many immature red cells in the blood stream. On admission, the patient had a low leukocytosis, and the blood counts were normal. Moreover, Von Jasch's syndrome, which is not thought to represent any pathologic entity, is simply a pathologic response. Most of the first episode can be explained, I think, by infection, possibly in the trachea, the bronchi or the interstitial tissues of the lung. At this time, there was no definite indication of cardiac abnormality. Examination of the heart was negative. No murmurs were heard, and there was no cyanosis. It is possible that the anemia at the time of admission might have accounted for the absence of cyanosis. However, when the anemia cleared, no cyanosis was mentioned, and I there-

fore assume that cyanosis was not present at that time. The patient did have a rapid pulse, —150,— but in an infant of six months that is not especially exciting. Any slight infection may increase the pulse up that high, so that I think we cannot say very much about the heart.

At the time of the second admission, eight days after discharge, there were several interesting new symptoms. The patient had become dyspneic, something not noticed before, and was definitely cyanotic. This was noticed by the child's mother. At the time of admission, the throat was congested, and there were rales in the lungs. The liver was definitely enlarged. Also, the blood findings were interesting because of the high leukocytosis with only 55 per cent polymorphonuclears. I find that a little hard to explain, but the fact that the next day the white-cell count had subsided to 18,000 with a much higher percentage of polymorphonuclears is a little more comforting and quite consistent with infection. The pulse, which was 160 to 170, was likewise consistent with infection. I think one of the most interesting facts was that, although the physical signs pointed to congestion and possibly consolidation of the lungs, the heart sounds were normal on physical examination, and no murmurs were heard. Ordinarily, with congestion of the lungs on the basis of cardiac failure, the x-ray picture shows cardiac enlargement, and almost invariably a murmur is heard. All this suggests that something in the lung might account for the symptoms and that the heart was not yet involved.

The statement was made in the x-ray report that the heart was normal in size and configuration. The mediastinum was apparently displaced somewhat to the left, but without shift on respiration. At fluoroscopy, there was no definite consolidation. I wonder if the patient could have had bronchopneumonia. Frequently, in bronchopneumonia, the x-ray picture is not too clear cut.

DR. MALLORY: We had the x-ray men review these plates, and they were unable to find any abnormality in the lung fields.

DR. WILLIAMS: There was nothing to account for rales. It has been said that bronchopneumonia of the interstitial type may produce definite signs on physical examination without showing much by x-ray examination. I hope that was so in this case. At any rate, bronchopneumonia in infants is a very common cause of cyanosis, especially if it has been present for some time. I had hoped to explain the cyanosis on the basis of bronchopneumonia.

How can we explain the terminal cardiac failure and possibly the cyanosis, if bronchopneumonia is out? First of all, rheumatic heart disease seems

extremely unlikely at this age, although it may have been reported in infants this young. The electrocardiogram showed a sinoauricular tachycardia, with a rate of 150, and a PR interval of 0.12 second, which is within normal limits for this age and heart rate. I consider rheumatic heart disease not very likely. If the patient had congenital heart disease, I find it difficult to make any single diagnosis. The absence of enlargement by x-ray and murmurs rules out a great many of the congenital heart lesions. I should say that this included primary idiopathic hypertrophy, interauricular septal defects, interventricular septal defects, patent ductus and other conditions. Ordinarily, most of these do not end in death at this early age, unless attended by some complication. I think that covers the group without cyanosis or with primary cyanosis. Then, in the moderate to extremely cyanotic group, I think the tetralogy of Fallot pulmonary atresia with transposition of the great vessels and other lesions are quite well ruled out by the absence of cyanosis at birth and of significant x-ray findings. However, one congenital defect that should be considered is origin of the left coronary artery from the pulmonary artery, which may give a picture consistent with this patient's story. The characteristics of this condition are freedom from symptoms during early weeks of life, with death usually occurring during the first year, and the prominent symptoms are cyanosis, dyspnea and sometimes chest pain, occasionally a peculiar kind of sweating, in which the infant sweats for no reason. That was seen in this case, but there may have been another reason for it. One thing very much against this diagnosis is the fact that in all the 8 cases in a series reported by White, Bland and Garland* the heart was enlarged for some time before death. That was not true in this patient. Also, in the cases in which an electrocardiogram was obtained, T wave changes were observed. Nothing was said about the T waves in this electrocardiogram.

DR PAUL D WHITE: Let me read the three electrocardiographic reports taken a few days apart, with Dr Porter's opinions.

Sinoauricular tachycardia, rate 150, PR interval of 0.12 second, moderate right axis deviation. The record indicates right ventricular strain, which suggests a congenital lesion or acute ventricular failure.

Sinoauricular tachycardia, rate 155, PR interval of 0.12 second, moderate right axis deviation, slight inversion of T₃. No significant change from the last record.

Sinoauricular tachycardia, rate 150, moderate right axis deviation, inverted T₃. No significant change from the last record.

*White P D, Bland E P and Garland J: Congenital anomaly of coronary artery: report of unusual case associated with cardiac hypertrophy. *Am Heart J* 8: 87-92, 1933.

DR WILLIAMS: I should think those findings would be against the diagnosis of origin of the left coronary artery from the pulmonary artery, which of course produces myocardial degeneration and hypertrophy, as well as electrocardiographic changes that are diagnostic.

Did this patient have endocarditis? There is nothing to support that diagnosis. The absence of murmurs, petechiae and so forth, as well as the absence—so far as one can tell—of an underlying valvular lesion, would be against it. One other thing that might explain the terminal failure is acute nephritis. It is well known that, in infants and young children, heart failure may follow acute nephritis without hypertension or without nitrogen retention. The one nonprotein nitrogen reported was normal. I presume that was done at the time of admission. It is possible that this patient had nitrogen retention later. Nothing is said about subsequent urines.

DR MALLORY: A second urinary examination ten days after the first was entirely negative.

DR WILLIAMS: Was that at the time of the first admission?

DR MALLORY: At the second admission.

DR WILLIAMS: That seems to throw out nephritis. Another disturbing point against the diagnosis of nephritis is the fact that there was no anemia during the second admission. Anemia is almost invariably present in acute nephritis in children. I wonder if some pulmonary lesion accounted for the cyanosis and produced secondary polycythemia and thus offset an anemia based on nephritis. Nephritis would also explain the acidosis, which may possibly have been due to a pulmonary lesion, however.

The electrocardiogram is not very much help at this age. One may see right axis deviation at six months of age in normal infants, but the axis is usually normal at this age.

When I read this over, my final diagnosis was question of bronchopneumonia, possibly following pertussis, with acute nephritis and cardiac failure. The negative urine findings are a bit upsetting, but I do not know how to explain the terminal cardiac failure otherwise because I cannot find, from the data given, any good evidence for a structural change or a congenital lesion that might account for it, accordingly, I shall have to leave it at that.

DR WHITE: Do you not believe Dr Porter paid more attention to the possibility of abnormality in the electrocardiogram? As noted in his very first statement, he was apparently impressed by the fact that there was a moderate degree of right axis deviation, and he said that later records showed

the same deviation. Did it suggest a congenital defect or right ventricular strain beyond what was expected at this age of six months? I think that may be of considerable importance.

DR. WILLIAMS: One thing I wondered was whether, at the time the electrocardiogram was taken, the patient already had enough acute right-sided failure to account for right-axis deviation. I found it very hard to account for on the basis of the usual things, such as pulmonary stenosis, the tetralogy of Fallot and conditions commonly known to produce right-axis deviation. I can see no evidence for acute cor pulmonale on any basis.

DR. WHITE: It is interesting that in the first year of life congenital heart defects cannot be ruled out readily and may be diagnosable only at a later date. I do not know what this youngster had, but the possibility remains that a congenital heart defect was present and did not show up until six months or more after birth, with the delayed appearance of clubbing and cyanosis and with more electrocardiographic right-axis deviation than usual.

DR. WILLIAMS: The clubbing was disturbing. I wondered if it was due to pulmonary involvement, which would also explain the heart failure. When these other things were fitted together, it left the field wide open. If there were a tetralogy of Fallot, it should give changes by x-ray examination. Could the terminal cyanosis have been due to auricular septal defect? One would then have a better explanation for the electrocardiogram without having to relate it to immediate strain and failure from other cause. Can one make a diagnosis of the tetralogy of Fallot in the absence of murmurs?

DR. WHITE: I think so, although I should hesitate, as in this case, to make the diagnosis of a structural cardiac defect during the first year of life without more proof, although such a condition should be considered possible.

DR. MARGARET M. GLENDY: There was one clinically interesting observation not brought out in the abstract. The child was admitted on Saturday afternoon. On Sunday morning, there were fine rales in the lungs, and the liver was only 3 cm. down. On Monday, it was down to the crest of the ilium. The cyanosis was present from the time of admission until death.

DR. WILLIAMS: I thought the rapid liver enlargement ought to be explained by progressive right-sided heart failure, but again the field is wide open.

DR. WHITE: There is only one x-ray report. The heart shadow might have become greatly enlarged before death and might have changed sig-

nificantly, as with the development of a pericardial effusion that might have caused a terminal tamponade.

DR. MALLORY: Dr. Edward F. Bland saw this case in consultation and made the following note:

I agree with the observations of others. Today, the patient is slightly cyanotic even in the oxygen tent. I hear no murmurs or gallop. In view of the cyanosis, the right-axis deviation and the globular-shaped heart by x-ray, I think he has congenital heart disease—probably a combination of defects, with patency of the septum (auricular) and possibly of the ductus as most likely. The prognosis is probably unfavorable.

He was at least correct in the last statement.

CLINICAL DIAGNOSES

Congenital heart disease.
Cardiac failure.

DR. WILLIAMS'S DIAGNOSES

Cardiac failure, right-sided.
Bronchopneumonia.
Acute nephritis.

ANATOMICAL DIAGNOSES

Congenital alveolar atelectasis.
Pulmonary arteriolar hypertrophy.
Cor pulmonale.
Chronic passive congestion of systemic circulation.

PATHOLOGICAL DISCUSSION

DR. MALLORY: Post-mortem examination showed a somewhat enlarged heart, with marked hypertrophy of the right ventricle. The right ventricle measured 5 mm. in thickness, which, even in an adult, is probable evidence of cor pulmonale. In an infant, it is an extreme degree. The left ventricle measured 6 mm. The lungs at the time of autopsy seemed reasonably well distended and aerated, although they were just a little subcrepitant. They were not edematous. It was obvious that there was cor pulmonale, for which there was no gross anatomical explanation.

On microscopic examination of the lungs, two things were obvious. The small pulmonary arteries were considerably thicker than normal. In fact, they looked like systemic, not like pulmonary, vessels. This thickening was due to true hypertrophy, primarily of the muscular layer of the wall. There was no endarteritis and no evidence of narrowing of the lumens, so that one must assume that pulmonary hypertension existed without primary vascular disease to explain it. Dr. Ronald C. Sniffen studied these vessels with

considerable care, measuring their internal and external diameters and calculating their ratios. The results from this case, from a similar one in another infant and from those of two control patients of the same age appear in Table 1. Three

TABLE 1. Ratios of External Diameter to Lumen Diameter

CASE	EXTERNAL DIAMETER OF VESSELS		
	600-1200 μ	450-550 μ	200-400 μ
Present case	18	25	24
Similar case	18	33	21
Control 1	13	14	15
Control 2	12	13	15

ranges of arterial size were studied in each case. The greatly increased thickness of the arterial walls, particularly in the smaller sizes of arterioles, is clearly brought out.

The lung parenchyma proved interesting in that there were practically no expanded alveoli and yet grossly the lung was not atelectatic. All the alveolar ducts and small bronchioles were grossly overexpanded so that the total amount of air in the alveoli was not much below normal. That is a very unusual form of atelectasis. It was uniform in all parts of all lobes. Ordinarily, with atelectasis, the alveolar ducts are collapsed, as well as the alveoli in the areas involved. Here the ducts were everywhere overdistended. In the collapsed alveoli, there were many accumulations of desquamated septal cells, which looked as if they had been present for a long time—I know of no way of estimating how long, but I am quite sure for longer than the duration of the final illness. It seems to me not impossible that this may even have gone back to birth and the patient had lived all these months ventilating only with his respiratory bronchioles. In any child dying a few days after birth, it is not uncommon to find large areas of lung tissue in which the alveoli have not expanded, and yet these lungs will transilluminate by x-ray in normal fashion.

DR WHITE: Is that the cause of death in these cases?

DR MALLORY: No; it is not. These children are not cyanotic, since some time can elapse before the child needs all his lung tissue to keep the blood oxygenized. The pediatricians may dispute this point, but I think Dr Sidney Farber would agree. I have seen one other case, which is identical, in a child of approximately the same age, but unfortunately, the clinical history was inadequate. It showed the same hypertrophy of all the pulmonary arteries and the same failure of expansion of alveoli, and I am strongly tempted to tie the two together. I think that the lack of expansion of alveoli is in some way responsible for pulmonary

hypertension and that the arterial changes are secondary. Dr. Williams's suspicion that the cardiac picture was in some way secondary to the pulmonary lesions is entirely correct.

DR WHITE: Has this clinical entity or syndrome been described yet, and are you going to put these two cases together?

DR MALLORY: I wish I knew more about the other case. We had only the heart and lungs, without any clinical findings to go with them.

DR WHITE: Was there any evidence of infection in this case?

DR MALLORY: No; we did find, in the myocardium, a few foci of lymphocytes. I suppose one could speak of myocarditis, although not enough to be of importance. I am sure there was no rheumatic fever.

DR WHITE: Was there acute right ventricular failure?

DR MALLORY: Yes

CASE 28402

PRESENTATION OF CASE

A fifty nine year-old Irish American unemployed man was admitted to the hospital because of pain in the lower abdomen and flanks.

Five months before entry, the patient was operated on in a community hospital for repair of bilateral inguinal hernias. He was discharged after an uneventful postoperative course of twenty-one days. After this, he experienced almost constant soreness and tenderness in the lower abdomen and flanks. He also had sufficient headache to keep him awake at night. About three months before entry, he had an attack of fever, for which his physician put him to bed for a week, with a special diet. The soreness and tenderness in the abdomen and flanks persisted. About a month later, a long dark blood clot was passed in the urine. Subsequently, several similar clots were passed. There were no other urinary complaints, and only occasional nocturia. There was a loss of about 18 pounds of weight during the illness.

The patient admitted the use of much beer and wine. The past history was otherwise irrelevant.

On admission, the patient appeared pale and thin. The tongue was beefy red and dry. The lungs seemed emphysematous. The heart was slightly enlarged to the left, with a moderately loud systolic murmur at the apex. Bilateral scars of recent herniorrhaphies were present. Both kidneys were palpable; the right was ballotable and down four to six fingerbreadths below the costal margin, whereas the left was down about one fingerbreadth. The costovertebral angles were

tender. The prostate felt firm and rubbery, and was of normal size. There was slight hypospadias of the glans.

The blood pressure was 140 systolic, 80 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood showed a red-cell count of 3,900,000 with 75 per cent hemoglobin, and a white-cell count of 14,500 with 76 per cent polymorphonuclears. The blood Hinton reaction was negative. The urine showed a specific gravity of 1.012, a +++ test for albumin, and many red cells and a few white cells in the sediment. The urine culture showed abundant growth of colon bacilli. The blood nonprotein nitrogen was 30 mg. per 100 cc.; the chloride was 97.5 milliequiv., and the bicarbonate 25.2 milliequiv. per liter; and the serum protein was 6.7 gm., the calcium 10.3 mg. and the phosphorus 7.0 mg. per 100 cc.

A roentgenogram of the chest showed multiple adhesions of the diaphragm and thickening of the pleura on the left side. The heart was slightly enlarged in the region of the left ventricle, and the aorta was tortuous, elongated and calcified. A flat film of the abdomen showed a clear psoas shadow on the right, and diminution in visibility of the shadow on the left. The right kidney shadow was obscured.

An intravenous pyelogram, taken in the Out Patient Department shortly before admission to the hospital, showed the right kidney outline to be indistinct and unusually large. The left was slightly larger than usual but of normal shape. An area of calcification overlay the upper pole of each kidney, consistent with costal cartilage. The left kidney showed normal excretion of dye and normal contour. The bladder appeared small. Both sacroiliac joints were fused.

On the day after admission, retrograde pyelography was attempted, without success. A roentgenogram showed the catheters to have extended to both renal pelves. The shadow of the right kidney seemed large.

Following cystoscopy and ureteral catheterization, the patient remained anuric for about twenty hours. The blood nonprotein nitrogen rose to 67 mg. per 100 cc. The temperature spiked to 103°F. for a few days, and then varied from 98 to 100°F. for the next two weeks. Urine gradually reappeared, but the output remained low. The urine was not bloody. There were occasional vomiting and nosebleeds. A blood culture grew colon bacilli in both flasks. For the first five days, the patient was given a daily intravenous infusion of 1500 cc. of 10 per cent glucose in physiologic saline solution.

The patient failed to improve. Although the urinary output increased satisfactorily, the nonprotein nitrogen of the blood rose to 158 mg. per 100 cc., and the chloride to 113 milliequiv. per liter; the bicarbonate fell to 17.0 milliequiv. per liter, and the protein to 5.1 gm. per 100 cc. The patient was therefore transfused in an attempt to raise the serum protein and improve kidney function. On the twenty-third hospital day, the temperature again began to spike, reaching 105°F. In the next week, the patient continued to do poorly. He complained of chest pain and was intermittently irrational. Slight dependent edema appeared. The urinary output continued fair, and the blood nonprotein nitrogen dropped to 97 mg. per 100 cc. Terminally, rales were heard in the chest, and Cheyne-Stokes respirations set in. Death occurred on the twenty-seventh hospital day.

DIFFERENTIAL DIAGNOSIS

DR. J. DELLINGER BARNEY: "Both kidneys were palpable; the right was ballotable and down four to six fingerbreadths below the costal margin." That may mean they were palpable because they were large or merely that they were low.

The tender costovertebral angles indicate an infectious process in or around the kidneys.

The blood studies show a certain degree of secondary anemia, and a moderate leukocytosis.

One would have to think of the possibility of nephritis or a polycystic kidney, and of tuberculous kidney or a bilateral tuberculosis. Tuberculosis can perhaps be excluded, because we generally get a sterile urine with tuberculosis. In this case, there were colon bacilli in the urine, and no instruments had been passed, so that there was no chance for external infection.

The very high phosphorus suggests uremia.

The right kidney shadow was obscured but apparently large on each of several examinations. I should like to know if the outline, so far as it could be seen, was regular or had lobules suggesting cysts, multiple or solitary, or neoplasm. We know more about the left kidney from the record than we do about the right. The left kidney showed normal excretion of dye and normal contour. Nothing is said about the right side.

DR. TRACY B. MALLORY: I think it is safe to assume that there was no excretion on the right side.

DR. BARNEY: If they succeeded in getting the catheters up to the renal pelves, I should like to know why they were unsuccessful in injecting dye into them.

From the story, one can safely say that the patient had a cystoscope reaction, which is not very common but does occur. Although, under certain

ditions, such a reaction might be considered avoidable, we must remember that at least one *hologic* kidney was present.

do not know that I can explain the nosebleeds, the vomiting may have been due to renal insufficiency. The high blood phosphorus and the high nonprotein nitrogen are confirmatory evidence. The patient had a colon-bacillus blood-stain infection, which might well have resulted in a primary renal infection. Intravenous infusion of glucose was given in an effort to overcome this infection and the anuria by re-establishing proper excretion of urine. Nevertheless, the nonprotein nitrogen climbed to 158 mg. per 100 cc. indicating that the process in the kidney was initially worse.

So far as the final episode is concerned, one must think of pneumonia, infarct of the lung and, possibly, pulmonary embolism.

Without going into all the details of this case, it seems to me that this man was well until after his hernias were repaired. He then began to get a little trouble. We do not know about the past history. Apparently, it was irrelevant. The patient had not had this trouble before. When he came to the hospital, it was found for the first time that he had certainly low and certainly enlarged kidneys. The costovertebral angles on each side were tender, and there was some infection, as shown by a certain amount of pus in the urine and the growth of colon bacilli from the urine. I should say that this kidney process involved particularly the right side, was of long standing and, after the hernia operation, flared up. The patient was cystoscoped, catheterized and so on, which made the matter still worse, and the kidney function fell off quite markedly. The infection in the kidneys continued, however, and he developed a generalized colon-bacillus infection.

The question is, What process would involve both kidneys and give a picture like this? We must consider a variety of things, particularly bilateral polycystic kidneys, in spite of the pyelogram. On one side, there was apparently normal excretion, and on the right side, — with the larger kidney, — there was no excretion of dye at all. I think polycystic kidney is not incompatible with the finding of a nonprotein nitrogen of 30 mg. per 100 cc. when the patient first came in. The left kidney might be doing enough work to compensate for the right kidney to a large extent, but not entirely. On the other hand, polycystic kidneys in a man of this age — fifty-nine — are unusual. Such patients often die earlier, and they generally have a previous history of hematuria, pain and infection.

But that would account for a good deal of the picture. Again, this may have been a simple cyst, but I do not believe such a cyst would put one kidney out of action.

Tumor must be considered. Again, new growth involving both kidneys is extremely rare. Tuberculosis, I think, can be ruled out because of the lack of symptoms, although there was evidence of old trouble in the chest, but not the symptoms one usually sees with renal tuberculosis, such as bladder irritability, and colon-bacillus infection is unusual with tuberculosis.

We must also consider pyonephrosis, with extensively damaged and infected kidneys. I think that there would have been a great deal more pus in the urine with such a condition and that, during some time before cystoscopy was performed, the patient would have had a higher temperature and more pain than is recorded. The possibility of lymphoma must not be forgotten. It might, in some bizarre way, involve both kidneys and perhaps give the picture that we have.

It is difficult to evaluate all the symptoms and put them together, but my first diagnosis is polycystic congenital kidneys.

DR. MALLORY: Would you like to see the x-ray films before you commit yourself?

DR. LAURENCE L. ROBBINS: This simply shows the large right kidney; the left kidney, so far as I can determine, is normal in size and shape and excretes the dye normally.

DR. BARNEY: The left kidney may, as you say, excrete the dye normally so far as it excretes it, but there is very little dye. There is no evidence whatever of pelvis or calyces on the right side. I believe that the kidney was extensively damaged. On that basis alone, it seems to me that a polycystic kidney can almost be ruled out. I think one can also rule out the possibility of tuberculosis, as well as nephrosis and pyonephrosis.

I cannot say anything better than polycystic kidney.

DR. WILLIAM B. BREED: You ruled out everything, did you not, Dr. Barney?

DR. BARNEY: Nearly.

DR. WILLIAM C. QUINBY: I should like to know why they could not make a pyelogram. They put the catheter high up. The point is just here, gentlemen: the outstanding assets of the urologist's diagnostic armamentarium are the cystoscope and the ability to make pyelograms by injecting opaque fluid through a ureteral catheter; if one does not do it and if one cannot give a reason why it was not done, the whole discussion is reduced

to a guessing match because no one would try to make a diagnosis without that evidence.

DR. MALLORY: I think, Dr. Quinby, that is merely putting the genitourinary surgeon on a par with the medical man. It is only fair once in a while to ask him to guess too, because the medical man is rarely able to visualize the pathologic lesions that he must diagnose.

DR. QUINBY: True enough, but if there is a direct way of making a pyelogram, why not do it? A medical man is not expected to make a diagnosis of cardiac lesions without an electrocardiogram.

DR. BREED: Is there some explanatory note, or is the person here who did the cystoscopy?

DR. MALLORY: No; but I assume that the patient was quite ill and, possibly, had some sort of reaction on the table, and they believed they could not continue.

DR. BARNEY: The retrograde pyelogram was unsuccessful. That is all we have to go by in the record.

CLINICAL DIAGNOSES

Bilateral pyelonephritis.

Pyonephrosis?

Uremia.

Bronchopneumonia.

Coronary heart disease.

Renal tumor?

DR. BARNEY'S DIAGNOSIS

Polycystic kidneys.

ANATOMICAL DIAGNOSES

Renal-cell carcinoma (hypernephroma type) of right kidney, with extension along renal vein into vena cava and with metastases to splenic vein.

Pyelonephritis, acute and chronic, left kidney.
Bacterial endocarditis, colon bacillus, aortic valve.
Cerebral infarct, septic.

Pleuritis, chronic fibrous, bilateral.

Operative scars: herniorrhaphy, bilateral.

PATHOLOGICAL DISCUSSION

DR. MALLORY: At autopsy, we found an extremely large kidney on the right, which was filled with tumor, a characteristic hypernephroma. In typical fashion, the tumor had grown up the renal vein, and a plug of tumor tissue protruded into the vena cava for a distance of 3 cm. This tumor thrombus in the cava was not large enough to cause obstruction, although, occasionally, real caval obstruction is produced in this way. An unusual and unexpected finding was a solitary metastasis in the splenic vein, which was completely occluded by the tumor. The other kidney showed a fairly severe pyelonephritis.

There was also a terminal bacterial endocarditis due to colon bacillus,—it will be recalled that the blood culture was positive,—and an embolus from the vegetation on the aortic valve had produced a small area of softening in the brain. There were old pleuritis and healed tuberculosis of the lungs, but no pulmonary metastases.

INSTRUCTION IN INDUSTRIAL MEDICINE

THE joint announcement of the Committees on Postgraduate Instruction and Industrial Health of the Massachusetts Medical Society in this issue of the *Journal* is a local expression of the widespread and growing consciousness of the importance of health in industry. This is not merely a medical awakening. While the medical profession, whose general interest has always been the preservation of health, is striving to orient itself, the industrialists, whose primary interest has heretofore been costs, production and quality of output, are likewise showing an appreciation of the

potential value of a physiologically sound employee.

Evidence of the interest of Massachusetts manufacturers is found in the current issue of *Industry*, the official organ of the Associated Industries of Massachusetts, where a series of twelve excellent and appropriate articles dealing with the health of workers is appearing. It is a safe prediction that before the passage of another year more than one physician in Massachusetts will be asked by an employer or personnel officer to give an opinion or discuss a problem that was suggested by one of this series of articles. The progressive physician should prepare himself.

Throughout the United States, the vital significance of industrial medicine has been recognized. Iowa has organized and presented an institute on industrial health; at Yale University, a series of ten weekly exercises will be given this fall; in Brooklyn, an intensive two week course has been announced, and so it goes. Alive and alert to all this, the Council on Industrial Health of the American Medical Association is keeping abreast, and serving in a particularly useful way by disseminating information from one part of the Nation to another.

The announcement referred to above asks that interested physicians mark November 7 on their calendars. Every doctor who is called into the manufacturing plants of his locality—especially into the smaller plants, and even though he is called but rarely—is an “interested physician,” and the role he plays may be exceedingly vital. It is now plain that the war is to be won or lost by a narrow margin, and this is a critical period in the battle of production.

LEGAL ASPECTS OF FIRST AID

A LETTER¹ in a recent issue of the *Journal* called attention to a situation that needs to be clarified. Will the lay persons who administer first aid run the risk of becoming defendants in lawsuits brought by dissatisfied victims of bombing or other disaster? No specific legislation has yet been passed, and any opinion advanced must be accepted

for what it is worth — that is, as a mere expression of belief regarding what the probable outcome of such lawsuits would be.

In the first place, it should be pointed out that those who administer first aid are liable to litigation, since "any aggrieved person, with or without cause, can file an action at law."² The validity of the suits will be decided by courts of law. Until the merits of such claims in the imminent, unprecedented circumstances have been assessed by the courts, it is reasonable to assume that the principles involved would be analogous to those in suits for malpractice brought against physicians.

A recent study³ of the problem poses several questions and attempts to give answers, which are admittedly not applicable universally. The first-aid worker would be reasonably protected if he followed rules accepted by the American Red Cross and the civilian-defense groups throughout the Nation. The necessary skill and precaution are defined as "such care as a reasonably prudent person should exercise, considering all the circumstances such as the injury itself, the entire situation of the emergency, [and] the training of the first aider." The authors' statement that those trained in first aid are probably under a legal duty to render such care seems unwarranted in view of the following statement by a recognized legal authority⁴: "No duty rests on a physician to accept an employment. He may refuse arbitrarily to engage his services." If a physician is not required by law to treat a patient, how can a different rule be applied to a first-aid worker?

Presumably, the layman trained in first aid has no more responsibility and is entitled to no less protection than the physician. Accordingly, the defense of the latter against litigation should apply equally to the former. And the specialist in legal medicine referred to above has this to say concerning the results of treatment, "A physician is not a guarantor either of his diagnosis or of his treatment, and the required negligence necessary for his liability is not made out by mere evidence of results of treatment or a failure to cure or a disappointing result."

Although it must again be emphasized that the layman's risk cannot be specifically assessed at present, it is apparent that anyone who follows conscientiously the accepted routine of first-aid treatment is in little danger of being successfully sued by the aggrieved recipient of his ministrations. Laws are passed to deal with situations that arise, and court decisions are based on the law, on precedent and on the human factors involved. Those who attempt to relieve suffering and save lives should have no fear that justice will tolerate unwarranted claims against them. Nevertheless, there is urgent need for statutes defining the rights and duties of civil-defense workers. These should be put into effect now — before the evil emergency is upon us.

MEDICAL EPONYM

ROENTGEN RAY

The discovery of the x-ray was announced at a meeting of the Physico-Medical Society in Würzburg in 1895. The paper by Wilhelm Conrad Roentgen (1845-1923), "Über eine neue Art von Strahlen (On a New Kind of Rays)," appeared in the *Sitzungsberichten der Würzburger physikalisch-medizinischen Gesellschaft* (1895, pp. 132-141). A portion of the translation follows:

If in a completely darkened room, one allows the discharges from a large Ruhmkorff coil to pass through a Hittorf vacuum tube (or a sufficiently evacuated Lenard's, Crookes's or other similar apparatus) and covers the tube with a rather closely fitting jacket made of thin black cardboard, a paper screen which has been painted with barium platinum cyanide will be seen to glow brightly and become fluorescent when brought near the apparatus. It makes no difference whether the painted or the unpainted side of the screen is turned toward the source of the discharge. . . . In the presence of this phenomenon one is first struck by the fact that some agent is passing through the black cardboard jacket — a jacket which will not allow the passage of either the visible or ultra-violet rays of the sun or the rays of an electric arc light; further, that this agent is able to generate a marked fluorescence. . . . It will be found that all bodies

are permeable to this agent, but in very different degrees. Paper is very permeable. Thick blocks of wood are also permeable. Sheets of hard rubber several centimeters in thickness still permit the rays* to pass through.

*For the sake of conciseness I should like to use the expression rays, and to distinguish them from others the name x rays.

MASSACHUSETTS MEDICAL SOCIETY

AMERICAN MEDICAL ASSOCIATION

After prolonged and intensive consideration, the Board of Trustees of the American Medical Association has come to the conclusion that the annual session of the association scheduled to be held in San Francisco in 1943 should be canceled. An official meeting of the House of Delegates will be held in Chicago at a time to be announced.

COMMITTEES ON POSTGRADUATE INSTRUCTION AND INDUSTRIAL HEALTH

On August 17, the Committee on Industrial Health voted to hold a comprehensive one-day program on industrial medicine, to be organized with the interests of general practitioners and part time industrial physicians in mind, and to be held, if possible, in co-operation with the Committee on Postgraduate Instruction. The two committees met in joint session on September 2, and are now collaborating on a program to be held on Saturday, November 7, morning, afternoon and evening, at the Harvard Club of Boston. The subjects to be discussed, the speakers and the dining and registration arrangements will be announced within a few weeks. Interested physicians are asked to mark the date on their calendars.

CASE HISTORY POST PARTUM HEMORRHAGE, FOLLOWED BY CEREBRAL HEMORRHAGE AND DEATH

A thirty five year old primipara at term had been seen routinely during a normal pregnancy. The past history was entirely irrelevant. She was delivered by low forceps, labor consuming eight

hours and being complicated in no way. The placenta was delivered spontaneously, and there was no hemorrhage. The blood pressure during labor was 90 systolic, 60 diastolic. The day following delivery, the patient developed a severe headache, and the blood pressure rose to 160 systolic, 90 diastolic. There was no note of convulsions. Hemiplegia developed soon after the onset of the headache, and death occurred three days later. Autopsy showed cerebral hemorrhage (basal ganglion and right internal capsule), subacute nephritis and fatty degeneration of the liver.

Comment. It is fortunate that an autopsy was performed, for the subacute nephritis and fatty degeneration of the liver are suggestive of a fulminating toxemia post partum as the basic cause of death. From the headache and increased blood pressure one might have inferred that an unusual post partum toxemia was responsible, but without the autopsy, the clinical diagnosis of cerebral hemorrhage would probably have been made. The value of the autopsy in this case illustrates how helpful it would be if autopsies were more frequently performed.

WAR ACTIVITIES

CIVILIAN DEFENSE

At a meeting of various members of the Medical Division, Massachusetts Committee on Public Safety, held at the Parker House, Boston, on August 26, the following matters were emphasized by Dr. A. William Reggio, the medical director:

1. Changes have been advised regarding the setup of medical first aid posts so that they may function more easily in conjunction with local conditions. It is suggested that the number of first aid posts in all communities be divided into first line active and second line reserve posts, that is, one half on the active list and the other half on the reserve list, because of the increasing shortage of physicians. It is also believed that if half the number of posts are active, well drilled, and completely manned and equipped, they can cope with almost any situation that may arise. This in no way should upset the present setup or disturb the work that has been done. It is merely a way of improving the setups and of somewhat lessening the strain on each community. It is also suggested that members of the dental profession be used more in these mobile posts, and in those communities where there are well trained veterinarians that they could also be utilized, with a little instruction. Practice sessions for these first line mobile posts are urgently recommended. In this way, it is also believed that a spirit of competition will arise as a result of which the second line reserve posts will feel a greater incentive to graduate from the reserve to the active list.

2. In those communities where emergency hospitals are established, at least one first aid post must operate from such a hospital. This in no way should upset the present setup in any community. It is merely an ad-

*Beginning with the October 15 issue of the *Journal* a resume of the maternal mortality in Massachusetts for the year 1941 will appear. It is planned to present an exhaustive analysis of this investigation; an article to be published each week for some time.

junct to the already existing posts and is a requirement laid down by the United States Office of Civilian Defense in Washington.

3. Before long, the regional medical heads will receive a number of certificates to be given to all members of the Medical Division already enrolled in the Massachusetts Committee on Public Safety. These certificates show evidence of the fact that the holder has been enrolled as a member of the United States Citizens' Defense Corps. The holding of such a certificate by each member is essential. The reason is that government supplies are now being allocated and will be distributed only to those communities in which every member of the Medical Division has been so enrolled. This in no way changes the status or allegiance to the state organization but is merely additional evidence of the fact that all members are also enrolled in the United States Citizens' Defense Corps as the second line to the Army and Navy.

4. The question of nonmedical deputies being appointed to sit and function in the report centers in some localities has been raised. It seems advisable to plan on this, owing again to the increasing scarcity of physicians. If such a nonmedical deputy is appointed, it is essential that the medical director's office be notified of his name, address and telephone number.

5. Since the Massachusetts terminology of medical setups differs somewhat from that used in the Office of Civilian Defense, a listing of the equivalent terms should help to avoid confusion in future communications. These are as follows:

MASSACHUSETTS	OFFICE OF CIVILIAN DEFENSE
Report center	Control center
Base hospital	Emergency base hospital
Emergency hospital	Casualty receiving hospital
Medical first-aid post	Mobile medical or Emergency Medical Service teams (2)
Stretcher bearers	Stretcher teams
First-aid party	First-aid squad
Chief medical officer	Local chief of Emergency Medical Service

CORRESPONDENCE

DEPRIVATION OF LICENSES

To the Editor: At a meeting of the Board of Registration in Medicine held September 16, the Board voted to suspend the license of Dr. Leo Leinwald, 1218 Commonwealth Avenue, Boston, because of gross professional misconduct in the practice of his profession as shown by false evidence in a court case.

REPORTS OF MEETINGS

BOSTON CITY HOSPITAL.

The fourth in the series of lectures on war medicine, sponsored by the Boston City Hospital House Officers' Association, was held at the hospital on May 14.

Dr. Maxwell Finland discussed "Communicable Respiratory Diseases in Wartime." It was emphasized that the streptococcus, although the commonest offender of the group, owes its importance largely to complications of the original infection. This has become especially true since the widespread use of the sulfonamide compounds.

Since World War I, but more especially in the early stages of the present war, many advances have been made in the understanding of these complications. The most significant observation is that the secondary invaders are usually a different type of streptococcus, especially in complications that occur later than ten days. They are really cross-infections, and should be so treated. Otitis media is still the commonest sequela. Prevention may be attempted by proper segregation according to types of organism, but even this is not entirely satisfactory.

The question always arises, When may scarlet fever be said to exist or to be epidemic? All the Group A streptococci are toxigenic to some extent, and whether a person will have the signs of tonsillitis or scarlet fever depends on the balance between the virulence of the organism and the resistance of the host. Therefore, there is always some scarlatina during streptococcal epidemics, and the same type of organism has been identified in the two kinds of manifestations of the same epidemic. The fact that the organisms causing the current cases of scarlet fever are of low toxicity will probably lead to more recurrences, for the formation of antibodies in such cases is poor. Such patients may remain positive to the Dick test and may fall prey to even slightly more potent streptococci. Recurrences have been reported in as high as 8 per cent of some epidemics.

Rheumatic fever is becoming more generally recognized as a definite sequela of streptococcal infections. But it is necessary to have a susceptible host and a certain unknown characteristic of the organisms to activate the process. Family background apparently plays a role. The incidence of complications in rheumatic fever is higher than physicians generally realize, especially if one observes the patient over a sufficiently long period with adequate tests.

Measles is the next most important communicable disease in army camps, largely because this supposedly innocuous exanthematous condition becomes more serious in such congregations of conglomerate groups of men. Epidemics occur invariably after a large influx of new men who are tired from the rigorous new life and are largely or partly from rural districts where measles has not been encountered. The seriousness of such epidemics is proportional to the number and severity of secondary infections. The streptococcus, which is the commonest secondary invader, attacks a respiratory tract whose entire length has been prepared by the preceding virus. Serious streptococcal pneumonias may be aborted by the proper use of chemotherapy, which should check the spread of virulent streptococci both in the individual respiratory tract and from person to person.

Influenza, it has been demonstrated, may be widespread without much disability or mortality, but a second wave, with its fearful secondary pneumonias, may be catastrophic. If the secondary invader is the pneumococcus, the prognosis is that of any well-treated lobar pneumonia, and the disease should not be serious since the ad-

of chemotherapy and the improvements in specific serum. In infections with the hemolytic streptococcus, which is the complicating organism following throat measles epidemics, the prognosis is not so favorable as with the sulfonamide drugs. But by far the most encouraging prospect is the widespread pulmonary necrosis that follows streptococcal invasion and gives every indication of being not only more prevalent but less amenable even the best forms of chemotherapy.

Lobar pneumonia is the most hopeful of all the communicable respiratory diseases since the advance of chemotherapy and serotherapy. The new fad of calling typical cases virus pneumonias is deprecated. Certain viruses are known to produce such pneumonitis particularly psittacosis and influenza but the last is the only common one. Most cases of influenza are now considered to be due to virus, since comparable syndromes are observed in the ferret, with widespread pathologic changes and no bacteria. By proper culture methods *aerophilus influenzae* can be demonstrated in the respiratory tracts of most people who are well or suffering from mild upper respiratory infections. Therefore this is very likely only a secondary invader.

The prevention of communicable respiratory diseases is still largely an unsolved problem. The gradual exposure of groups rather than sudden exposure of whole camps does not appear practical in the sudden expansion program. Proper spacing in barracks and hospitals and the placing of beds with alternate heads reversed in case the necessary distance for bacteria to travel and materially alter the incidence of infection. The most valuable and difficult task is to decrease the carrier rate. Although previous sprays have not seemed effective a new amacidin spray compound appears promising. The early liberal use of sulfonamide drugs may prove an abortive power, at least in streptococcal spread. Wholesale inoculation with the specific pneumococcal carbohydrate may be effective if such an epidemic is being caused by one type. Probably the most important group to attack is the medical personnel, who are apt to be careless. Vacations during respiratory infections should be advocated or it is not possible, special masking and careful hygiene precautions. The importance of dust is ever increasing. A fine oil spray may prevent easy spread and various germicides sprayed around during bedmaking have met with indifferent success. The use of ultraviolet light as a barrier between beds shows promise for airborne infection only. Eating utensils are a prime source of cross-infection unless properly cleaned, and such cleaning includes running hot water when possible.

The definitive treatment of this group of infections is actually the early and adequate use of the sulfonamide compounds and other drugs. For the intelligent and successful therapy of any infection, the responsible bacterium must be specifically identified. Whereas the pneumococcal pneumonias require only three or four days of intensive therapy, a streptococcal pneumonia with fluid may require one or two weeks or longer. In general, sulfadiazine is the most effective drug, largely because of its greater bacteriostatic effect, but also because of its considerably lesser toxicity, which permits more intensive and prolonged therapy.

The consequence of cross-infections even in supposedly clean hospital wards was demonstrated by the development of pneumonias from a different type of pneumococcus in patients convalescing from an original one. In other places, as high as 25 to 35 per cent of patients in clean wards developed positive streptococcal cultures

in their throats, especially during the second and third weeks of convalescence.

BOSTON ORTHOPEDIC CLUB

The annual spring clinic and meeting of the Boston Orthopedic Club was held on May 18, with Dr O to J Hermann presiding. The afternoon clinic on various aspects of surgery of the hand was held at the Boston City Hospital.

The first paper, delivered by Dr J Edward Flynn, of the Boston City Hospital, discussed Dissections of the Fascial Spaces of the Hand. It was concluded from careful examination of over a hundred dissected hands post mortem that there are always clearly defined mid palmar and thenar spaces. In no case was there absence of the dividing septum. In discussing this paper Dr Sterling Bunnell, of San Francisco the guest of honor, pointed out that this accurate investigation completely settles any previous conflicts in the anatomy of the fascial spaces. In Dupuytren's contractures, this septum demonstrated by Dr Flynn is greatly accentuated.

The second presentation, by Dr Edward Hamlin, Jr., of the Massachusetts General Hospital was entitled The Innervation of the Hand. His conclusions were based on end results from a group of cases at that hospital, in which the outcome was considered good if the patient was able to resume his usual occupation or carry on every day life satisfactorily. In 147 cases, involving the repair of all nerves about 80 per cent were in this category. This is somewhat better than most series, and the best results were obtained in repair of the ulnar nerve, also contrary to the general rule. Both results may be explained on the paucity of injured radial nerves in the group. Furthermore the relative unimportance of the intrinsic muscles of the hand helps to explain the good ulnar results. In general it was found that motor function eventually returned if there was sensory regeneration. One consistently poor result was in the adductor of the fifth finger, probably because of carelessness in splinting.

In repair of an ulnar nerve, sensory function is the primary consideration. Six of these 55 cases became septic without ill effects. Age apparently was not a factor. The time when repair was carried out was in consequential within broad limits. Of 9 cases in which repair was carried out in less than six hours, 8 were successful, whereas 11 of 17 cases repaired after one month were also successful. Four of the latter were done after more than two years, and 1 after more than four years. The average rate of regeneration was 12 mm daily, with extremes of 0.5 and 35 mm. In the unsutured nerves studied regeneration began at eleven weeks and was complete in thirty six weeks.

In median nerve injuries repair was successful in 82 per cent of cases. That function of the opponens pollicis muscle is not always an infallible test of function when a laceration occurs at the wrist is borne out by the fact that this was normal in 6 such cases. This probably indicates that the muscle is innervated separately or by a twig given off above the wrist. The rate of regeneration was the same as that of the ulnar nerve, and, again, age played no part. However, results became poorer as the time interval between injury and repair increased.

The few cases of radial nerve injury afforded good results in 78 per cent. Results in the recent period, however, were much better than formerly.

In nerve injuries associated with fractures, surgery was seldom required. Good results were obtained in 96 per

cent of cases, and the failures were due to gross inefficiency. It was instructive to learn that such injury followed rather than preceded open reduction of a fracture in some cases. This suggests that although identification of a nerve at operation is an admirable procedure, unnecessary retraction or manipulation merely leads to trouble.

Heretofore, there have been no satisfactory tests of prognosis in nerve injury, and this is a vital phase of the problem. Electrical excitability still affords the best means of evaluating this status of a nerve, and a new use of the galvanic, in contrast to the faradic, current (devised by Dr. Arthur L. Watkins) promises improved predictions regarding the need of operative repair.

Nothing new in nerve-repair technic has been added. It is believed that twisting is of minor importance unless of marked degree. In old cases, the neuroma must be resected and the nerve freed up as much as necessary to prevent tension during regeneration. Splinting is indispensable for the prevention of tension and of the loss of tone in the denervated muscles.

In his discussion of this paper, Dr. Bunnell stated that he had found sepsis of more consequence than here intimated. Furthermore, he considers lack of rotation critical, especially near the field of distribution of a nerve, where the bundles begin to have a definite place. Absence of opponens paralysis in median-nerve laceration is explained by a shift of innervation.

The next paper, by Dr. Henry C. Marble, of the Massachusetts General Hospital, entitled "Infections of the Hand," was devoted to some commonly overlooked problems in this vast field.

The staphylococcal carbuncles and different types of abscesses are usually easily recognized. The streptococcal infections are known to be a wildly spreading process, often heightened dangerously in hospital personnel by human passage. The septic human-bite wound is now being better understood but is still usually seen too late because of the alcoholic euphoria of so many of these patients.

Vaccination has not infrequently been mistaken for chancre or some serious ulcer. Gonococcal tenosynovitis closely simulates that caused by the streptococcus, there being no trauma. This is common in genitoinfectious-disease clinics but is rarely recognized in a hand clinic. About half the cases of nontraumatic tenosynovitis fall in this category when proper studies are done. If there is any suspicion or when there is a tenosynovitis of questionable etiology, a proper bacteriologic setup should be available in the operating room. If this diagnosis is confirmed, any incision should be closed without drainage.

The classic tuberculous joint involvement, with grating crepitation and fluctuation above and below the carpal ligament, is a relatively late stage. At any stage, the problem is essentially a medical one. Dr. Marble now advocates merely splinting and bed rest, the former choice of treatment, surgery, being retained for later use, if necessary.

Fungus infections are becoming increasingly common, and are particularly significant when secondary infection, with its concomitant cellulitis and other sequelae, occurs. This may prove an important field for the use of the relatively new, gramicidin treatment.

An unusual but difficult and interesting injury to treat is the "grease-gun hand," in which grease is pushed into the tissues under tremendous force. These injuries are probably best widely débrided if seen early, but unfortunately they are not often painful or otherwise troublesome for some days or at least hours.

In discussion, Dr. Bunnell stated that he still employs surgery for the eradication of tuberculosis, using wide and careful dissection. The chief advantage is one of speed in convalescence, but even this form may require months of postoperative immobilization. For tenosynovitis, he now employs a "trapdoor" incision over the site of tenderness, in addition to one in the cul-de-sac in the palm. However, it may be possible in the future, with the aid of chemotherapy, merely to carry out the latter incision.

In the next paper, Dr. Champ Lyons, of the Massachusetts General Hospital, discussed "Chemotherapy of Hand Infections." The efficacy of any such treatment is proportional to the accuracy of the bacteriologic diagnosis and the intelligence employed in selecting the kind and amount of drug. Cultures should be incubated at proper temperatures: for example, finger-tip bacteria may grow only under their natural conditions of room temperature. Probably the most valuable single aid is a proper anaerobic medium, of which there are now several simple and efficient ones. Of the streptococci, Groups A, B, C and G all respond to the sulfonamide drugs. Group A, which is the commonest human pathogen, responds to the usual dosage in a short time, but the others should be exposed to higher levels for longer periods. Group D, of which the enterococci are important members, is nonresponsive and is best attacked by zinc peroxide. The staphylococcus, in general, is resistant unless all dead tissue is removed and the drugs are used locally. Human-bite infections, caused by fusobacteria and diphtheroids, are locally necrotic lesions that are treated best by wide débridement. If this is well done, the role of chemotherapy becomes minor. But sulfadiazine in small amounts over long periods has proved efficacious and is even better locally than zinc peroxide. Anthrax lesions respond well to sulfadiazine, but the malignant form should have supplementary specific antibacterial serum therapy. Actinomycosis has now been demonstrated to respond to sulfonamide therapy if this is continued for six to twelve months. Close follow-up examinations are advisable.

In employing local chemotherapy, one should understand that the mechanism of action is not the same as when the drugs are systemically administered. Several factors are involved. The solubility of sulfonamide drugs in serum varies greatly, sulfanilamide being about ten times as soluble as the others and on that account the drug of choice. But the persistence of drug as a foreign body and its cytotoxicity demand consideration. Sulfanilamide is most rapidly absorbed, whereas sulfapyridine has a strong foreign-body reaction. Although sulfathiazole is generally more bacteriostatic and of minor foreign-body irritation, it is highly cytotoxic. This is often overlooked when it is mixed with sulfanilamide. Sulfadiazine is midway between the extremes in all respects and is probably best used as an adjuvant to sulfanilamide, in a 25 per cent solution, especially when dressings are to be more than three days apart.

The final paper of the afternoon, by Dr. William E. Browne, of the Carney Hospital, was entitled "Dupuytren's Contracture." It was emphasized that trauma probably plays a definite etiologic role in certain cases. The pathologic changes usually involve the reticulum layer of the skin as well as the fascia, and skin grafts are therefore often necessary. In dissection, the careful excision of all ramifications of the fascia, especially the deep penetrating ones, is essential. Especial care should be taken to avoid injury to the underlying nerves and vessels and to preserve those supplying the digits.

discussing this paper, Dr Bunnell stated that trauma of direct consequence in pathogenesis. Surgery merely reproduce the original condition unless great is exerted. Certain cases may need stage operations, enotomy may help as an initial procedure. Of the benefit in the postoperative care is the immobilization of the proximal joints.

An evening meeting was held at the Boston Medical Society. Dr Sterling Bunnell, of San Francisco, discussing 'Instruction of the Hand,' emphasized the fact that it is 50 per cent of hand injuries are industrial and ensation cases, in which good eventual functional and immediate saving of time are urgent. Intelligent and well-conceived early treatment may prevent loss of the later loss of time and function that is common in neglected cases. Two of the most valuable factors accomplishing the desired results are the covering of the affected area with skin, even if a flap is necessary, and positioning of the part in the position of function: everything except the affected part is kept in motion.

Any surgeon engaged in this field should be trained in orthopedics, plastic surgery and neurosurgery. In general, tendons used in transplants should be of the same as those lost, or improper function may well result. Operations in this field, one must guard against the tendency to open areas of potential infection.

On the original examination of the part, exact figures on amount of function should be recorded, as the result of active and passive motions. The cause of limitation of function, whether nerve, vascular, bone or joint, should be accurately determined and recorded. In general, operations should be carried out in proper stages. Repair of tendons and skin, which requires immobilization of the member, should be done before that of tendons, which demands mobilization relatively early. Every procedure should be considered from the standpoint of its worth while for the patient, doctor and insurance company. All operations on the hand should be carried out under a tourniquet and in an atraumatic fashion. The hand is 'unbridled' by excision of all flexion contractures. The necessary underlying scar tissue. This also greatly involves the nutrition of the member. Internal scars must be removed en bloc, for these contract just as superficial ones do. Scars of secondary repair should be placed to prevent subsequent contractures and the possibility of dysfunction if keloids form. Although the latter ability of healing is certainly racial and familial to a certain extent, there is increasing evidence that chronic irritation of an early scar probably plays a part.

The appropriate selection of the type of skin graft to be employed and its proper use are very important. On the whole, Reverdin grafts are practically never used, for recipient scar is never strong and may break down on continual usage. Thin Thiersch grafts have many of the vital skin structures missing and very often contract later. But those taken with the Padgett dermatome, thickness of 20/1000 of an inch are about the proper thickness for they will develop subcutaneous fat and slide in necessary. It is preferable to employ full thickness skin where there is a possibility of sepsis. The tube type graft is more aseptic than the buried graft and is therefore more frequently used. In placing the skin, one should continually guard against stretching until the skin is white, for in such circumstances the graft will be lost soon afterward. Probably as essential as any single procedure in skin grafting is the guarding against hema-

toma by adequate hemostasis, proper drainage, constant and even pressure, and immobilization.

Nerves account for about 50 per cent of the function of the hand, and their early repair is therefore imperative. All severed nerves as far as the distal crease of the hand should be repaired. No axones are lost, and repair will result in regeneration if nutrition is good. Regeneration of nerves severed above the wrist requires approximately thirteen months, whereas that from wrist to finger tip consumes about seven months. This is about a finger segment a month. Regeneration of sensory nerves occurs irrespective of the time of repair up to about five years, whereas that of motor nerves is more problematical. However, there is nothing to be lost by trying a repair in all cases. In motor nerves, fibrous regeneration starts immediately, but there is little chance of success once response to electrical stimulation is lost. Age is of little significance in nerve regeneration, but nutrition of the part is of the utmost necessity. Nerves should never be immobilized on tension, for this will result in ischemia, with temporary or permanent paresis. In tendon lengthening, the joints are flexed successively and then later extended, starting with the proximal one. Nerve grafts have been successful in selected cases. This procedure is more effective in the smaller, better vascularized nerves, and the sural nerve has proved convenient and of the proper size for the donor site. One should always be careful not to allow axons outside the neurolemma lest subsequent neuromas occur.

Tendons are probably next in consequence to nerves in the hand. Since they do not function in a scar bed, even though they are intact, the scar is removed, and a graft is inserted. One may accomplish this by placing a fascial strip with its slick side toward the tendon, or by the use of the specialized fatty tissue known as paratendon. The best sources of this are over the triceps tendon or under the deep fascia of the thigh. If the area is too cicatricial, an entire tendon assembly in the form of tendon and paratendon from the palmaris longus or dorsum of the foot may be transplanted. The healing of tendon occurs in the following stages: at the end of two weeks, there is connective tissue union, at the end of three weeks, tendon fibers are growing but are not strong, and at the end of four weeks, the tendon fibers are strong. Immobilization does not add to the strength early but looks better, and is therefore usually carried out. But mobilization definitely adds to the strength later. Therefore, the best procedure is to immobilize for about fifteen days to bring about junction without undue reaction and adhesions. Then, the hand is mobilized for strength.

Tendon grafts account for about one third of all operations on tendons. They are usually carried out because of retraction, resection at the time of the original operation, poor tissue or the position of the injury (pulley). The small tendons encountered in the hand require no particular precautions, but large ones need fascia on both sides for nourishment. The palmaris longus tendon is present in 80 per cent of people. The extensor tendons of the toes may be employed, but the brevis should be left for function.

Moving pictures were presented showing the method of suturing tendons at a distance—a method whereby the proximal end is kept from retracting and a few fine silk sutures are all that is required to maintain approximation of the cut ends. Pull-out sutures, which allow strong suture material to be used and later removed after the tendon is firmly healed, are employed.

In conclusion, it was pointed out that the capsulectomy form of arthroplasty is good only for proximal joint fixation, for, in distal joints, instability results. This was in answer to a question concerning the treatment of fixation of disuse. For best stabilization of the wrist joint, removal of the proximal carpal row was suggested.

BOOK REVIEWS

Nephritis. By Leopold Lichtwitz, M.D. 8°, cloth, 328 pp., with 62 illustrations. New York: Grune and Stratton, 1942. \$5.50.

Every physician interested in nephritis may well read this book with interest and profit. No other volume in English affords the kind and amount of information that it contains. It is necessary to point out however, that this is due to the fact that it expresses a highly individualistic and personal point of view—that of Lichtwitz on the kidney. It embodies no comprehensive review of present-day American viewpoints. Furthermore, its point of view, however valid it may be, is one that was reached some years ago. Most of the investigative data on which it is based were gathered before 1925. Of the four hundred and fifty bibliographic references, fewer than thirty concern work done since 1935.

The mere fact that the anatomic studies of such men as Jean Oliver and the clinical and physiologic work of investigators like Goldblatt and his followers, Page, Smith and his collaborators and dozens of others are all but ignored does not detract from the worth of the volume if it is accepted for what it is; the omissions are deliberate. One may be permitted to doubt, however, whether the patient with nephritis will live longer or more comfortably if handled according to Lichtwitz than if treated as he would be treated in any modern American clinic, or even that the state of his kidneys will be better understood. On the other hand, it is refreshing to read a book that totally dispenses with the current pseudomathematical formulas and carefully abstruse jargon of the renal physiologists.

The Principles of Neurological Surgery. By Loyal Davis, M.D., Ph.D., D.Sc. (Hon.). Second edition, thoroughly revised. 8°, cloth, 503 pp., with 154 illustrations. Philadelphia: Lea and Febiger, 1942. \$7.00.

The aim of this book is to give to the average physician and student an insight into what may be accomplished by neurologic surgery as a means of treating nervous diseases. The special branch of surgery dealing with the nervous system is of such recent development that this is one of the first textbooks to deal with the subject as a whole. The author has condensed into a book of moderate size his own experience and the monographic literature on the subject. The result is a sound book, sufficiently detailed for practical purposes and broadly based enough to be of value to all neurosurgeons. The volume reflects, moreover, the rapid strides in neurologic surgery since Horsley removed a cord tumor and Keen a brain tumor, fifty years ago.

The first chapter on diagnosis is the weakest part of the book and might well be omitted from future editions. Subsequent chapters on craniocerebral injuries, tumors, and spinal-cord and peripheral-nerve injuries are sound. The surgery of the autonomic nervous system, epileptiform seizures and essential hypertension are also considered, but with less sureness. The illustrations are adequate. If, as the author, hopes, this book will give the practitioner a better insight into these complicated problems and allow

the patient with operable lesions to reach the hands of the surgeon more quickly, the volume will justify its publication.

A Manual of Allergy for General Practitioners. By Melvin B. Cohen, M.D. 12°, cloth, 156 pp. New York: Paul R. Hoeber, Incorporated, 1941. \$2.00.

The boundaries of the field of allergy are still so amorphous that it is extremely easy for the writer of a book on the subject to go astray. We are all familiar with the type of book whose author has been carried away by the esoteric and melodramatic aspects of his cases. The skillful detective work evokes the admiration of the reader but also leaves a residue of doubt and disbelief. The everyday, common-sense practitioner is suspicious of thaumaturgy, since it is not given to most of us to work very many miracles in an ordinary lifetime.

Other books on allergy have lost themselves in the morass of immunology, a subject in which the general practitioner is rarely certain of his depth.

Dr. Cohen has skillfully avoided these mistakes. He has packed an extraordinary amount of useful information into a small space. His style is clear, his definitions satisfying, and his common sense everywhere apparent. Occasionally, in some aspects of the subject,—especially on the importance of bone scorings, taken as an index of active allergy,—there is still some difference of opinion. On the other hand, a small manual is not an arena for controversial subjects, and a rare statement more dogmatic than the circumstances warrant may not be out of place.

For the student or general practitioner who has not yet invested in a textbook of allergy, this manual is an excellent introduction to the subject. For those who wish a working knowledge of allergy, it will more than suffice.

Perineopelvic Anatomy from the Proctologist's Viewpoint. By R. V. Gorsch, M.D. 8°, cloth, 298 pp., with 157 illustrations. New York: The Tillingham Company, 1941. \$8.00.

This is not a textbook of surgical technic but an authoritative monograph of the applied anatomy of the perineum and pelvis from the proctologist's viewpoint. Dr. Lynch, in his foreword, identifies the author as one who is advanced in knowledge of the pelvic outlet.

The text is divided into nine chapters, dealing respectively with the pelvis and pelvic floor, the anal canal, the anorectal musculature, the levatores ani, the rectum and sigmoid, the perineopelvic spaces, the pelvic fascia, the pelvic lymphatics and the nerve supply to the colon, rectum and anal canal. There is a bibliography of selected references at the close of each chapter. The work is based on the author's experience in the practice and teaching of proctology and on a series of excellent personal dissections represented, with some additions from other sources, by many admirable illustrations, some of which are full-page plates, two in colors.

One is glad to note that Dr. Gorsch retains the term "triangular ligament" instead of the misleading modern term "urogenital diaphragm." The occasional errors, which creep into any text, no matter how carefully prepared, will undoubtedly be corrected in a second edition. From the anatomist's standpoint, the work is virtually perfect, and the author is to be congratulated on its successful performance. It will be of lasting value to proctologists and anatomists alike.

FIVE-YEAR STUDY OF CESAREAN SECTIONS IN MASSACHUSETTS*

ROBERT L. DeNORMANDIE, M.D.

BOSTON

THE completion of the five-year study of cesarean sections in Massachusetts (1937-1941), sponsored by the Massachusetts Department of Public Health and the Section of Obstetrics and Gynecology of the Massachusetts Medical Society, allows one to summarize the findings and draw

Over the five-year period, 11,030 cesarean sections and 87 hysterotomies were performed, a total of 11,117 abdominal deliveries. One abdominal pregnancy is not included in this report.

Table 1 shows that 45 per cent of the cesarean sections were emergency and 54 per cent elective

conclusions that might appear arbitrary if based on the statistics of any single year.

The statistics were compiled from replies to sample questionnaires sent to all licensed maternity hospitals, and yearly reports¹⁻⁵ have already been published.

The total number of births reported in Massachusetts during the five years was 333,731, of which 272,752 occurred in hospitals. The percentage of abdominal deliveries was 3.3. It is interesting to note the increase in the number of births occurring in hospitals each year.

operations, with the type not reported in less than 1 per cent. There were more low than classical type operations, but the ratio is not significant. The extraperitoneal and Porro operations account for about 1 per cent each. Sixty-five per cent of the patients were operated on before labor began, but 82 per cent were operated on with membranes unruptured.

The percentage of sections to the total number of deliveries has varied from 3.1 to 3.4 during the entire five years.

Table 2 gives the indications for the 87 hysterotomies. The large majority of these indications seem to be sound. A grave mistake occurred in 2 cases, in which the diagnosis was wrong and a

*Presented at the annual meeting of the Massachusetts Medical Society, on May 27, 1942.

hysterotomy was done unnecessarily. It is doubtful if the indications "severe bleeding" and "placenta previa at three and a half months" were justifiable.

In Table 3 are recorded the types of anesthesia. Nitrous oxide, oxygen and ether is the type most

ing a normal delivery, but when a study of the questionnaires reveals that in many of the elective sections the babies were very small and obviously premature, it is evident that the time of operation was badly chosen.

I shall speak later of the questionable judgment

11 deaths have to be recorded as due to the anesthetic.

In each year's study, operations resulting in the deaths of babies have been analyzed under emergency and elective sections. In the emergency classification, 741 babies were lost, and in the elective group 245—a total of 986. To analyze all the indications for the five years would be a lengthy process, but it must be noted that almost 50 per cent of infants were lost because of placenta previa or separated placenta. One questions the advisability of many of these operations, for they were done at six or seven months' gestation and could undoubtedly have been managed satisfactorily by vagina.

It must also be noted that many babies died or were stillborn following elective sections. It is fair to assume that some would have died follow-

tops the list. In this group, many babies were lost from prematurity because the operation was done by election too early in the gestation or because labor had begun prematurely. These possibilities must be kept in mind in all repeat sections. The next largest group comprises patients with a contracted pelvis or disproportion. In many cases, this indication was probably justified, for it was frequently noted that a baby weighed under six pounds, and often the patient did not even go into labor.

About the next two indications, placenta previa and separated placenta, one can only say that there was bleeding. Many of these babies were lost. The number of patients operated on at six and a half to seven months raises the question whether all these sections were necessary. The frequency of fetal malformations in cases

placenta previa makes an x-ray examination advisable before operation for this indication. The majority of operations in the next group is because of an increasing, severe toxemia. Many of these pregnancies were allowed to continue too long, with the result that some of the

necessity for operation. If the cervix has been amputated, it should be known before labor begins, and an elective section performed.

Under "associated medical condition," the largest group was for cardiac conditions. The necessity or even the advisability of operating in many

mothers died. One cannot help believing that if there were more careful prenatal care, fewer patients would be operated on for this indication.

It is surprising that eclampsia should have been an indication in 53 cases. Eleven mothers (21 per cent) and 9 babies were lost, a very high mortality.

An increasing number of sections occurred for each presentation. Many of the patients were multiparas, and the babies were of moderate size. It is obvious that when any malposition appeared, there was little attempt to manage it by vagina.

Under "dystocia," I have included the so-called "stagnant labor" cases. In the latter part of the study, there were many more attempts to give the patient a test of labor. Some cases of so-called "stagnant labor" had no labor whatsoever.

The majority of sections because of previous surgical operations were for repairs of the perineum and cervix. Again, there is no way of judging the

cardiac cases is open to question, for it is known that such patients often have short, easy labors. With careful management, they may be better delivered by vagina. Careful consideration of all factors is necessary before the decision to operate on a cardiac case is made.

Kidney complications, central-nervous-system disease and tuberculosis were some of the other medical indications. Because one clinic believes that many diabetic patients should be delivered by section, the frequency of this indication has increased.

If operation seems indicated with a history of previous obstetric disaster or difficult operative delivery, it should be elective or should follow a short test of labor under careful supervision. Labor for eighteen to twenty-four hours without progress, followed by an emergency operation, should never occur with this indication.

It is impossible to judge whether all the elderly primiparas required sections. If the indication is real, however, it should be an elective, not an emergency, section.

Obstructing tumors should be discovered by careful prenatal examination, and operation for

For the next indication, "malformation of fetus," 19 sections were done with a known malformation present. Accompanying this indication, there was no statement that the patient had a contracted pelvis. Unless there is some other indication, section on a known malformation seems to be

this indication should also be elective, not emergency, as often happened.

Only 3 babies were lost following section for fetal distress, and 5 for prolapsed cord. One wonders whether the fetal distress was real. Undoubtedly, cesarean section for prolapsed cord will save a certain number of babies, but the infant mortality rate for this indication was 18 per cent.

A section following operative attempts at delivery is a serious procedure. Although a certain number of mothers and babies may be saved, the mortality rate is high. In this group of 35 patients, 10 mothers and 11 babies died.

I cannot consider the next indication justifiable. Yet 73 operations were done at the request of the patient or for sterilization.

Comment on the indication "ruptured uterus" is unnecessary, for the patient with this condition must, of course, be operated on as quickly as possible.

Under "abnormality of genitourinary tract," a surprising number were bicornate uteri.

"Twins" was the recorded indication in but 10 cases. Many other cases of twins occurred, but the operation was for some other indication. In a few of these, "disproportion" was given as the indication, no x-ray film was taken, and twins were delivered. There were 2 cases of triplets.

The indication, "postmaturity," is specious, especially when, as happened several times in this series, a baby weighing 7 pounds or less was delivered.

entirely unwarranted. The surgeon should ask himself whether he would like his wife to be operated on for a known malformation of the fetus incompatible with life; I think the answer is clear. No religious dogma demands that a section be done under these circumstances. In 1 case in which a section was done, the hydrocephalic head was so large that it had to be punctured before it could be removed from the uterine incision.

Under "unengaged or floating head," 8 cases were operated on without any labor, again an unjustifiable procedure.

If congenital dislocation of the femur has so narrowed the pelvis that a baby cannot be delivered through it, that indication is of course real. The same thing is true of fractured pelvis.

It is unnecessary to go through each of the other indications. It is seen at once that some are questionable. Under the heading, "bizarre," 150 cases have been grouped. A few will serve as examples: "pregnancy at term," "Braxton-Hicks contractions," "highly nervous state of the mother," "pain in right hip" and "threatened placenta previa." I might go on with many other equally bizarre indications.

Table 5 presents a summary of the maternal deaths. In making this study concurrently with the five-year study of maternal mortality in Massachusetts, it has been possible to obtain data concerning the deaths from cesarean section from the

ernal-mortality investigations of the same cases, which were made by physicians in personal interviews. This has given a much more accurate picture of the cesarean deaths than the questionnaires would have revealed. As a result, in many cases, the causes of death given on the questionnaires have been found inaccurate, and the causes of death from the maternal-mortality schedules have been accepted.

Over the five-year period, there were 273 deaths. Of these, 74.7 per cent followed emergency operations, and 25.2 per cent followed elective sections. Over patients were lost following low than classical sections, but I am inclined to think that the reason the classical type was performed more frequently is that it can be done more quickly in an emergency.

Eleven patients, or 4 per cent, died following extra-peritoneal operations. Some were undoubtedly selected cases. Others were under observation by competent physicians the entire time, and yet they were allowed to remain in labor so long that the physicians were forced to do extra-peritoneal operations resulting in death. In this operation, there is danger of opening the bladder or cutting the ureter, as was done in this group.

Fifty per cent of the deaths followed a Porro operation. The majority of these were done for prostatic or an atonic uterus.

Table 6 shows the causes of the maternal deaths. A total of 273 deaths gives a mortality rate of

TABLE 6. Causes of Death in Cesarean Sections.

16 per cent, a remarkably good record. I doubt any other state has excelled it. Analysis of the deaths, however, shows some disturbing facts.

One hundred and six patients, or 39 per cent, died from sepsis. Of these, 24, or 23 per cent, were elective sections. It was in these cases that most of the changes were made in the causes of death. The following history is typical. Immediately following operation the patient's temperature and pulse rose. There was distention, vomiting and delirium, and death followed. The questionnaire gave the cause of death as "toxic myocarditis, vasomotor collapse and paralytic ileus." Interview by the investigator in the maternal mortality study brought out the true facts. The desire to cover up the diagnosis of sepsis led to improper certification of the cause of death.

Hemorrhage accounted for 32 deaths, or 11 per cent. The majority of these followed section for either placenta previa or separated placenta. Often, when a section has been done for separated placenta and bleeding continues, a quick decision must be made whether or not to remove the uterus to save the patient. In several cases, the uterus failed to react, and yet the surgeon did not remove it. Several patients died from postpartum hemorrhage two or three hours after operation, which suggests a lack of careful nursing supervision.

There were 28 deaths, or 10 per cent, from embolus. Some of these patients had a definitely septic chart, and although the death was undoubtedly due to embolus, it might well be classed in the septic group.

Shock was given as the cause of death in 25 cases, or 9 per cent. It was frequently difficult to determine whether death should be assigned to shock or to hemorrhage.

In many of these fatal cases, no donors were provided for transfusion. In one case, the operation was done by a general surgeon; the patient bled profusely during the operation and continued to bleed afterward; yet the surgeon left the hospital as soon as possible after the operation, and made no attempt to stop the bleeding. The local physician was unable to cope with the situation, and the patient died from postpartum hemorrhage. On the whole, however, the use of transfusion has been gratifying and has undoubtedly saved many lives.

The death of 11 patients, or 4 per cent, from anesthesia is a serious criticism. Careful anesthesia must be provided in all cases. I have already spoken of the cases of eclampsia and toxemia. Some of the latter were elective sections, and the patients should not have been lost.

The deaths from acute respiratory infections were accidents and could have been avoided only by the most meticulous care.

Of the anaphylactic deaths, 1 resulted from what is called "pituitary shock." The other 5 were classified as due to improper matching of blood. That statement must now be revised in the light of the recent work on the Rh antibody.

It is fair to state that these reactions may have been due to this newly discovered factor.

That 4 deaths should have been caused by intestinal obstruction was undoubtedly due to lack of keen observation on the surgeon's part.

In the cases of acute pulmonary edema, it is noted that the patients were operated on after they had been in labor a very long time.

Although only 3 deaths were assigned to premature separation of the placenta, this complication occurred in some cases in which the death was assigned to other causes.

The miscellaneous list of 12 causes of death needs little explanation. The scarlet-fever case was apparently true scarlet fever, and the surgical emergency was one in which there was an aneurysm of the splenic artery, which ruptured. In the death assigned to acute yellow atrophy, the patient had an unusual blood condition and bled from the gums, stomach and other mucous membranes. The uremic case was one in which the patient had had one kidney removed, developed toxemia during pregnancy and gradually failed, with an increasing nonprotein nitrogen. The death assigned to carcinoma was that of a patient whose entire pelvis was involved with cancer, the section being done to save the baby.

* * *

This is the largest series of cesarean sections ever reported from one community, so far as I have determined, and the results are remarkably good. Examining them superficially, one could not criticize them. But on analysis, one must conclude that many unnecessary cesareans were done. Because of this, the number of repeat sections will continue to increase and will always give a certain number of deaths. The same criticism is true regarding the indication "contracted pelvis or disproportion." There is no doubt that many physicians do not carefully study each case. Cesarean section is an easy way out of a

difficulty, but it often has serious consequences for the mother in future pregnancies.

The fact that nearly 40 per cent of the patients died from sepsis is a very serious criticism of the medical profession. It shows conclusively that there was either error in technic or in the choice of a method of delivery. In some cases, when a low or classical section followed a long labor, sulfanilamide was used in the abdomen. Many of these patients eventually recovered, even though the convalescence was stormy. It is conceivable that this will become a routine treatment in emergency cesareans with a possibility of infection, and that the percentage of septic deaths may thereby be greatly reduced.

The maternal mortality rate for these cesarean sections, 2.46 per cent, was low, but when one realizes that in the maternal-mortality study, cesarean section figured in nearly 20 per cent of the deaths, it is evident that such deaths are a potent factor in keeping the State maternal mortality higher than it should be.

In closing, I want to thank the hospitals that co-operated so splendidly in making out their questionnaires. It added a great deal to the work of their record rooms. In nearly all cases, it was well done, and the true facts were reported. Only in a few cases was there lack of co-operation; this occurred chiefly when the physician obviously wished to cover up poor obstetrics.

Under the new law making the Department of Public Health responsible for licensing all hospitals, and with an investigator checking their records and procedures, one can look forward confidently to even better results.

TRAUMA OF THE SKIN DUE TO WARTIME ACTIVITIES*

JOHN G. DOWNING, M D †

BOSTON

IN emergency came, and we were found wanting. It must never happen again! Preparedness must be our watchword, not only for defense but also for offense when the opportunity arises. Physicians must be prepared to relieve and prevent injuries due to wartime activities. No longer may the specialist be content to confine his study to the immediate realm of his specialty—he should be trained for any emergency. While lay persons, because of their attendance at various courses, are busy talking of poisonous gases and first aid, many medical men still remain ignorant of some of the essentials of both.

Care of the skin is vital at present. During the Spanish Civil War, cutaneous disease caused much suffering and disability in civil and military populations, and helped to decide the outcome of the war. The same diseases played a great part in World War I.

Medicine has learned lessons from these experiences, but there are still many pitfalls to be avoided. It has been stated that in war will be one of industry and production. The producers must therefore be kept healthy—namely, occupational diseases, of which dermatoses comprise 60 per cent, must be prevented. President Roosevelt, in a recent newspaper interview, expressed his alarm over this aspect of industry: 9,000,000 man days of work lost; 101,800 persons killed; 350,000 permanently disabled—1 out of every 14 workers, most of them from twenty-one to forty-four years of age, or enough to build several battleships or equip several regiments. The president hoped that everyone would reflect on these figures, so that the situation might be remedied or at least improved, and he must have had medical men particularly in mind.

New plants are being equipped, and old plants are experimenting with substitutes, new chemicals and chemical processes. Speed is essential to fill contracts within specified time limits, but reckless haste results in disaster. Overcrowding in factories and in the housing of workers must be avoided. Although the older and larger plants are properly prepared, others lack adequate preventive methods, such as means of ventilation and exhausts, and many factories have no facilities for the personal hygiene of the workers and no medical supervision. Too few physicians are prop-

erly trained to cope with these problems, and still fewer have sufficient knowledge of industrial poisons. Recent events created a national emergency that subordinated the welfare of the individual to that of the Nation. Nevertheless, it behooves the physician to watch the individual, for each person affected may be a warning of the imminence of an epidemic of disabling dermatitis of physical, chemical or infectious origin, whether in civil, industrial or military life. At present, it may seem strange to assert that, of the three groups, the industrial is the most important. Yet it is reasonable to believe that the loss of one key worker may delay the necessary equipment of many fighters. Hilliard¹ points to the need of a public health program and states that there are the same possibilities of reducing sickness among industrialists who congregate daily as there are in preventing diseases in the general community. At present, the most essential wartime industrial activities are the manufacture of garments, machinery, tools and explosives, aircraft production and shipbuilding.

OCCUPATIONAL DERMATOSES

Recognition of an industrial dermatitis may often prevent similar occurrences in military life. For example, an outbreak of dermatitis in a plant making raincoats was shown to be due to free sulfur. To hasten production, the rubber was semicured, resulting in the release of the free sulfur and causing erythema and intense itching of the skin of many employees. Such coats would have irritated the soldiers wearing them.

In another plant manufacturing rubber goods, it was found that the old rubber cement could not stand the intense heat essential for the rapid turnover, and a new cement was therefore introduced. The cementers encircled a wad of the rubber cement around their right index fingers and applied it to the seams and edges. They suffered a dermatitis consisting of edema, desquamation and fissuring of the fingers, with extension of a sensitization eruption over the hands and arms, with resulting disability and loss of production.

In April, 1940, I investigated the cause of an epidemic of cutaneous diseases among boys and men wearing new fabrics. Each eruption started with marked erythema and edema of the penis and then of the scrotum; later, vesicles and wheals appeared on the loins, and the rash frequently be-

came generalized. It was accompanied by such intense pruritus that one patient became temporarily violently insane, so that it was necessary to commit him to a psychopathic hospital. The

FIGURE 1. *Painful Heels due to Cement in Shoes.*

The skin appears white and sodden, like boiled meat. A physician suffering from this disturbance was willing to undergo a sympathectomy for relief; change of footwear avoided this.

causative factor was found to be a new synthetic resin finish that had previously affected the employees in textile industries. The same finish had

FIGURE 2. *Leather Dermatitis.*

An eruption on the distal half of the dorsum of the foot should suggest such a diagnosis, rather than that of a fungus infection.

been applied to cloth intended for the army personnel, but was withdrawn and not issued after this investigation. It would have caused more disability than a horde of Japanese.

In another textile plant, two workers handling indigo cloth for sailors' blouses suffered a dermatitis from a change of the formula. Sensitivi-

ties to these clothes should be kept in mind, for they are already appearing in the coast guard and naval personnel.

Shoe workers are still suffering from hazards incident to their trade, and eruptions are occasionally seen from footwear (Figs. 1 and 2). These patients are usually treated for fungus infections, owing to mistakes in diagnosis.

Among machinists and their helpers, dermatides from cutting oils have become unnecessarily numerous (Fig. 3). The cutaneous manifestations have been of two types: mechanical interference with bodily function, that is, folliculitis, and the reaction of hypersensitivity, that is, eczema. In the first group, the skin becomes dry and scaly,

FIGURE 3. *Folliculitis from Cutting Oils.*

The skin shows a breaking off of the hairs, papules and pustules.

and the lanugo hairs break off at the point of emergence from the follicles, leaving a black-dot appearance; comedones result from the collection of epithelial debris and dirt; later, acuminate papules, which become secondarily infected and form pustules, furuncles and large abscesses, appear. These heal with scars varying from smooth pigmented atrophy to large keloids. In the second group, the eczematous dermatitis is localized or generalized. Men assembling small parts work with their hands close together and suffer erythematous, dry, fissured eruptions of the hands, because of constant contact with the drying oil. In the assembling of large parts, the oil splashes on their arms and clothing, and the eruption appears on the arms, especially in the antecubital spaces and on the abdomen and the anterior aspects of the thighs. Admixtures such as terpenes, creosols, acids and alkalis are usually the sensitizers. Minute pricks from metal chips produce portals of entry for bacteria, with resulting pyoderma. Cancers are infrequent.

Similar eruptions appear in workers exposed to chlorinated naphthalene, such as men handling

bles containing halowax used for insulation of wires. This is especially true in poorly ventilated places, as in ships under construction. In these exposures, the workers must be watched because of the danger of systemic poisoning. Six electricians working in a submarine developed yellowish, wax-like milia on the sides of the neck, the lobes of the ears and the cheeks, accompanied by comedones, papules, pustules and nodules (Fig. 4).

FIGURE 4. *Acneform Eruption from Halowax.*

The skin shows yellowish, wax-like milia, comedones, papules, pustules, and nodules.

Two had similar lesions on the forearms and hands. No systemic disturbances were discovered after careful physical examination and laboratory studies.

In the manufacture of explosives, trouble rarely occurs among the older employees, but new workers, who may not be immune and who do not realize the danger in handling the various materials, sometimes neglect to take the proper precautions. Dinitrotoluol and the nitrates, especially ammonium nitrate, are cutaneous irritants, and the workers who mix them develop a dermatitis. Fulminate of mercury is used in the making of detonators and percussion caps. Workers exposed to this compound may show signs of mercurial absorption, and those who perspire freely may suffer an affection of the skin of the neck, behind the ears, of the face and in the antecubital spaces. There is inflammation of the nasal mucous mem-

brane, the skin is discolored, and there may be shallow ulcerations at the tips of the fingers that are relieved by 10 per cent sodium hyposulfite. Tetryl and trinitromethyl nitramine also cause eruptions among new workers. An eczematous dermatitis appears at the edges of the respirators and the volar surfaces of the forearms. Two types of cutaneous eruptions may appear: mechanical interference because of the penetration of the dust into the follicles and the microscopic punctured wounds caused by the sharpness of the crystals; and sensitization dermatitis—that is the chemical may be dissolved in the fluid from the seboregic areas and produce inflammation of the skin, most marked in those areas.²

Trinitrotoluene causes a marked deep-orange staining of the skin, by which it is readily absorbed. In the summer of 1919, I treated many cases of poisoning contracted in unloading depth bombs, but only a few cases of active dermatitis were observed. One of those affected was seen two years later, when he was operated on for what was thought to be gall-bladder disease but was actually yellow atrophy of the liver. Trinitrotoluene causes a blue hue on the gums similar to the blue line caused by lead poisoning. This disappears after removal from exposure.³ A few hours' exposure on a hot day often results in cyanosis, with marked blue-ness of the lips. Dinitrophenol causes not only local but also systemic disturbances. Explosives, especially those containing potassium dichromate, also affect the mucous membranes, causing perforation of the nasal septum. Nickel and chrome plating are frequent causes of dermatitis. Substitutes are being used in every plant; for example, benzol is now being employed for toluol and may result in blood dyscrasias and cutaneous hemorrhages. Hydrofluoric acid, mercury and magnesium are widely used and all affect the skin.

In airplane manufacture, the agents responsible are: all the halogens; the fish oil, covering the duraluminum, which is laden with bacteria; volatile substances from the paint shop, thinners, dope, special formulas, fumes, varnishes, solvents, gasoline, dryers, asphalts, dyes and oils; and cutting oils in the machine shops (neutral petroleum with free sulfuric acid). Contact with acids, iron oxide, emery, rottenstone and chrome polishing agents may be injurious.⁴ Chromic acid compounds cause punched-out ulcerations of the skin and nose, as well as eczema. All the above apply as well to the shipbuilding industry.

In military life, the possibilities for cutaneous diseases are similar to those of industrial and civilian life, varying from sensitivity to clothing and baker's eczema from cinnamon powder or the

persulfates to burns from explosives and gases and infections regarded in civil life as trivial and belonging to the unwashed. However, in military encampments, especially on active service, these diseases become of major consequence, owing to close crowding of men and lack of suitable bathing facilities. *Pediculosis vestimentorum capitis* and *pubis*, rarely seen in private practice, infested the personnel of entire camps during the last war, causing great discomfort and severe secondary infections, and were carriers of disease. It is difficult to guard against the single soldier who unknowingly introduces this parasite into a camp. Scabies also caused the loss of many man-days, through failure to recognize the disease and through over-treatment. Scabies alone may be only disconcerting and not disabling, but when combined with sepsis it causes real disability. Every persistent or widespread *furunculosis* should be regarded as having scabies as a background until such a basis is disproved. *Ecthyma* and severe *pyodermia* may result from parasitic infestation.

Fungus infections of the skin are already becoming a problem in the various camps. Before the last war, such infections were endemic in various parts of the tropics. Hence, it was brought by seasoned veterans to training camps, and widespread infection occurred. In turn, these men on discharge brought it to their various communities. The original foci appear harmless: an area of maceration between the toes, especially in the fourth interspace, a few deep-seated vesicles on the central arch of the foot, a yellowish hyperkeratosis under the anterior arch, or a thickened toenail plate may be overlooked or passed over by the examining medical officer. One such focus may infect a whole company. This focus, after a long march or days of sleeping with shoes on, may assume alarming proportions, resulting in the so-called "trench feet" of the last war, or a lymphangitis, an encircling erysipeloid eruption of the lower legs, a phlebitis, inguinal adenitis or even a cellulitis, with resulting serious illness. The fissures caused by fungus infections are frequently portals of entry for streptococci and staphylococci. In this war, world wide as it is, medical officers should be cognizant of fungus infections. At least, they should know those endemic to the neighborhood of their camp, a necessity made evident by the recent outbreak of coccidiosis at a camp in California.³

EXPLOSIVES AND GASES

Medical officers and personnel are being trained to cope with the more obvious products of modern warfare, the dangers of explosives and gases. These men are equipped and have adequate protection against gases known to exist, and are therefore

ready for any such onslaught; civilian physicians and populations should likewise be informed, trained and equipped. Bit by bit, we are losing our sense of security derived from distance, but this distance still seems to nourish the hope that it would not be worth while to transport wartime gases so far. Why not? They certainly would be sure and as effectual as incendiary bombs. Such an unfamiliar danger could cause great terror and panic. A hit is not necessary—dropping the gas in the vicinity of a plant is enough to disrupt its production at least temporarily. Its effectiveness was demonstrated in the last war. Why have they not been used in this war? It cannot be because of previous treaties, all of which have been flouted; it cannot be because of fear of retaliation, for no such fear on the part of the aggressor has as yet been apparent; it cannot be because of solicitude for the civilian populations, for the bombing of Rotterdam and Coventry belies any such solicitude. It is probably because the rapidity of action to date would make the most valuable gases, the persistent ones, more dangerous to the user than to the enemy; or perhaps up to date the aggressors have not felt the need of these gases and are holding them in reserve in case of necessity. Perhaps the element of surprise, which seems essential in this conflict, would be lacking, for unless the aggressors have developed a new gas they believe that the civilian and military populations are prepared. The time may come when necessity or opportunity or a new discovery will determine their use. I believe that warfare gases will be used on the civilian populations rather than the military, and it consequently behooves physicians to keep informed of progress in this field.

Although many thousands of gases were investigated up to 1918, only a few were found to be effectual, and almost without exception these contained bromine or chlorine atoms. They are effective because of their irritant or destructive action on the skin and mucous membranes. The five most deadly ones are mustard gas (dichlorethyl sulfide), lewisite (vinylchlorazene), phosgene, chloropicrin and bromobenzyl cyanide. Lewisite was not used in the last war. Most of the gases are liquids that, when dispensed as droplets, persist for a long time. Mustard gas, which was the most widely used and was the most effectual, causing the greatest damage to the skin, penetrates paint, woodwork, porous material, shellac, paper, wax, leather and ordinary clothing. Oilskin clothing and synthetic rubber are penetrated slowly.⁴ It belongs to the vesicant group—that is, those that cause vesiculation or blistering of the skin. They all present a similar clinical picture—erythema in the folds of the skin, most marked about the geni-

neck and axillae, vesicles and bullae appearing idly. The depth of penetration varies. Persons differ in their sensitivities and reactions to these, so that the lesions may range from simple ulceration to necroses, depending also on the concentration and period of exposure.

Mustard gas and lewisite are the most important vesicants. The former causes edema of the gums, pseudomembranous pharyngitis and detachment of cells and tissue. In civilian populations, chemical warfare is more complicated because of the different ages of the population, and on account of various diseases. Early symptoms may be sneezing only; gradually, the throat becomes irritated. In about twelve hours, there is a discharge of mucus from the nose. At the same time, the early cutaneous lesions appear. The older burns are more frequent and insidious, and appear slowly. They are erythematous plaques resembling sunburn. After a while, the central portion desquamates, leaving a slight weeping surface, without any actual blister formation. The most serious lesions are likely to be severe, and are followed by erythematous patches covered with large bullae containing a serous or seropurulent fluid. They occur on the flexor surfaces, particularly about the scrotum, and are frequently preceded by small pustules surrounding the hairs. The pain is commonly severe. Occasionally, necrosis occurs. Itching replaces the pain and may persist indefinitely, being continued by a traumatic neurosis. I have three veterans under treatment who, since 1918, have had pruritus due to mustard-gas burns. Lewisite acts more quickly on the human skin. The latent period is only fifteen to thirty minutes. Its minimum irritant concentration is below its perceptibility through odor. It is apparently absorbed through the skin, causing systemic poisoning. At first, there is a slight burning sensation. After thirty minutes, erythema of the skin occurs and increases gradually. After three hours, areas from 12 to 15 cm. are affected. After thirteen hours, numerous blisters, cherry size and smaller, appear and gradually coalesce in one large blister,⁷ which later becomes surrounded by an erythematous halo. These areas may slough down to the muscles, and unlike mustard gas, which usually leaves only atrophy, lewisite may result in deep scarring. The pain accompanying these burns is usually severe. I have already seen one patient with a burn from lewisite. He was an instructor who demonstrated the art of sniffing once too often. He showed marked erythema and desquamation of the skin on the face and neck. Death may occur from both gases, but more frequently results from lewisite.

Burns from caustics have been seen particularly from sodium hydroxide, which causes lesions varying from a few vesicles to deep ulcerations (Fig. 5). With the maintenance of military secrets, it

FIGURE 5. Punched-out Lesions from Caustics.

is impossible for the outside physician to know exactly what the exposure is, but careful scrutiny of the skin—especially of the hands for yellow, brown or gray stains, or a bluish appearance of the mucous membranes, or punctate hemorrhages—will lead to the suspicion of systemic poisoning.

PREVENTION

Most occupational dermatoses can be prevented. Hazards must be detected and eliminated. Mechanical devices should replace manual contacts, and when this is impossible, gloves should be worn; when gloves cannot be worn, protective liquids or creams should be tried. Such creams must be selected with care, for they can cause eruptions. Workers exposed to irritants and oils should be taught the value of cleanliness, not only of themselves but also of their benches and machines, and of removing the grime before meals and of applying an emollient at bedtime, and again before starting work. Periodic instruction to foremen is highly recommended; they should be taught the need of careful supervision of their men and women workers, so as to prevent them from discarding gloves and from using dangerous short cuts to speed up piecework, such as dumping articles in bowls of acids or caustics and removing them by hand instead of by tool, as well as using fingers, cloths or sponges in place of brushes.⁸ They should watch for signs of fatigue or carelessness or recklessness, all of which are the chief causes of many injuries. Hazardous processes should be safeguarded whenever possible. No new substances should be introduced until their possible effects on the workers have been thoroughly studied. In

many cases, dangerous chemicals are preferred to less irritating ones because of their lower cost—for example, the use of benzene instead of naphtha; moreover, since many chemicals are not now available, substitutes must be used. No worker should be compelled or permitted to keep his hands wet with any solution for hours at a time, for few skins can stand constant wetting. Such jobs should be alternated during the day with those in which the hands must be kept dry. Young workers, notably those under twenty years of age, should not be employed in hazardous occupations, such as the manufacture of explosives.

In military medicine, the best method of prevention is the instruction of medical officers in the early recognition of dermatoses, careful inspection of newcomers to camp and segregation of those with contagious cutaneous disease. Treatment of these diseases should be by recognized, proved therapy. Experimental work should not be tried at military camps, but at home by those who are unable to enter active service. Perforce, much will be learned, by accident or by mistakes. It is already known not only that the sulfanilamides are neither bactericidal nor fungicidal but also that both organisms will grow in their presence. They must be used with care, especially in persons who have industrial exposure to magnesium or sulfate. I have seen one case of a generalized dermatitis following the ingestion of two tablets of sulfathiazole in a worker who had such an exposure. Whether this was due to a peculiar idiosyncrasy of the patient who had never taken any medication or to this exposure is impossible to state. Their use locally should be limited to fresh preparations or those sterilized.

Physicians must be alert to the dangers of epidemics, especially in communities near military encampments. They should be experts in first aid and should have a fundamental knowledge of wartime gases. The civilian population should be taught what to do in such raids. Minutes are important. With lewisite, preventive treatment must be started immediately. By the time a patient reaches a hospital or a decontamination station, it is too late. Civilians must be taught sensible methods, and just as every household is now informed what to do in case of an incendiary bomb, so too each one should be taught the essential measures to be taken immediately in case of a gas attack, for their own protection and for the relief of others. All these directions may be learned from several pamphlets, the most recent

and thorough being the one published by the United States Office of Civilian Defense and entitled *Protection Against Gas*. A can of kerosene, a bottle of hydrogen peroxide and a package of bleaching powder or pail of soapy water, timely and properly used, may save lives.

* * *

A knowledge of dermatology, always important in civilian life, is most essential in industrial and military organizations. Dermatologists have already demonstrated their value in industry. They promoted the Council on Industrial Health of the American Medical Association, pointed out many serious hazards, and suggested methods to prevent them and ways to relieve those affected. The last war taught the value of specialization. In military life, dermatologists should be assigned to their specialty and given an opportunity to teach other medical officers the prevention, diagnosis and treatment of cutaneous diseases. It may not sound very serious to mistake a case of dermatitis due to a hypersensitivity to clothing for a case of scabies or vice versa, but wrong treatment might be serious to the victim as well as to the service when a few days' disability is extended to weeks or months, with great loss of manpower. The training of dermatologists in syphilology should place them in charge of the control and the diagnosis and treatment of this disease. The danger of new and unknown poisons and diseases, against which there is no defense and about which experience alone can teach one, will be ever present in this conflict, so that a constant need of medical literature on these subjects will arise. Hence, the value of continuing medical publications and medical meetings for the dissemination of recent experiences and results is evident. The dangers of the present conflict should be a challenge to the entire medical profession, who should not fear these dangers but should be prepared and willing to share any exposure, hardship or risk to attain the ultimate objective—victory.

RETENTION OF A RUBBER TUBE IN THE BILIARY TRACT

Report of a Case

PETER A. CONSALES, M.D.*

BOSTON

THE purpose of this article is to report a case in which a rubber tube was retained for four and a half years in a choledochoduodenostomy communication without any untoward symptoms and with, eventually, the expulsion of the tube and complete restoration of the biliary-duodenal continuity.

CASE REPORT

A 36-year-old married woman was admitted to the Malden Hospital on January 17, 1937, with the complaint of jaundice, itching of the skin and pain in the upper abdomen for the previous 3½ years. There had been marked increase of jaundice, itching and pain for 6 weeks prior to admission. The stools, which heretofore had been clay colored during the attacks and light yellow during the interim, had been clay colored for the preceding weeks.

The patient dated her present complaints to about a year following her first operation, which was performed elsewhere in May, 1932. The gall bladder containing stones was removed, after which there was drainage of bile for 5 months. The wound then healed, and the patient remained in good health for several months. In June, 1933, approximately a year after the cholecystectomy, the upper abdominal pain, jaundice and itching of the skin recurred. The jaundice lasted 2 or 3 weeks and was accompanied by intense pain and itchiness, with clay-colored stools and dark-brown urine. Following each attack, the patient was symptom free for a similar period. To relieve her condition, a second operation was performed on October 31, 1933, at another hospital, and a side-to-side choledochoduodenostomy was performed for complete occlusion of the common duct in the second part of its course.

After this operation, the patient was symptom free for about 8 months, when the symptoms of which she previously complained gradually reappeared. At first moderate, the intermittent attacks of pain, jaundice and itching became quite frequent and prolonged on each attack. For 6 weeks before admission, the patient had been quite ill, having had no relief whatsoever. Her skin had become deeper bronze, and the epigastric discomfort and pain with chills became persistent. At times, the pain, chills, fever and insomnia were so marked and vomiting so severe that the patient had to remain in bed for days. Finally, she sought relief because her condition became progressively worse.

Physical examination revealed a very thin and moderately emaciated woman, markedly jaundiced. The scleras and skin had a deeply bronzed appearance. There were no enlarged lymph nodes. The heart and lungs were essentially normal. The blood pressure was 112/64, the pulse 66, and the respirations 18. The temperature was 98.6°F. The abdomen was rather soft and scaphoid, and revealed a firmly healed incision, about 13 cm. long, below and parallel to the right costal arch. Palpation elicited a definite area of tenderness, moderate muscular spasm

and rigidity above and to the right of the umbilicus. No masses were felt. The liver was very much enlarged and easily palpable, and extended almost to the brim of the right pelvis; the spleen was not enlarged. Many streaked abrasions were present on the arms, legs and body, denoting continuous scratching. Her weight was 121 pounds—39 pounds below her usual weight.

On admission to the hospital, the value for hemoglobin was 80 per cent (Sahli); the red-cell count was 3,500,000, and the white-cell count 9000. The icteric index was 100, as compared with the normal value of 5, and the serum bilirubin (van den Bergh reaction) was 82.5 mg. per 100 cc. The bleeding time was 4½ minutes; clotting began in 5 minutes and was complete in 6 minutes. The blood

FIGURE 1.

This film, taken thirteen weeks after operation, shows extensive filling of the bile ducts and liver radicles immediately following the injection of Hippuran solution through the T tube. Small amounts of the opaque material are visible in the duodenum.

Wassermann reaction was negative. Urine specimens contained a large amount of bile, and the stools were clay colored. A flat x-ray plate of the abdomen revealed no visible calculus in the gall ducts, but the liver was moderately enlarged.

In view of the history and the physical and laboratory findings, a diagnosis of an obstructed choledochoduodenostomy stoma was made, and operation was advised to restore the flow of bile into the intestinal tract. Hypodermoclysis of 500 cc. of 5 per cent glucose twice daily and 15 gr. (1 gm.) of calcium chloride daily were given for 3 days, and on the day prior to operation 475 cc. of citrated blood was given.

*Associate in surgery, St. Elizabeth's Hospital, Brighton

The operation was performed under nitrous oxide, oxygen and ether on January 21, 1937. A Mayo-Robson incision through skin and fascia was carried out; the rectus muscle was divided longitudinally, and the peritoneum opened. Omental adhesions were released from the parietal peritoneum and also from the anterior surface

in Morrison's pouch, and the T tube and drain brought out through a stab wound lateral to the incision. The abdomen was closed in layers, No. 2 chromic catgut being used for the peritoneum and fascia; four stay sutures of silkworm gut were inserted, and the skin was sutured with silkworm gut interruptedly. The operation lasted 85 minutes, and the patient was in excellent condition at its termination. She was given intravenous glucose, and the T tube connected with tubing was brought into a bottle at the side of the bed.

The postoperative course was uneventful. There was slight elevation of temperature for the first 3 days, but the general condition was greatly improved. The appetite was good, the skin took on a lighter hue, and scratching gradually subsided to a minimum degree; the feces, which had taken on a yellowish color 24 hours after the operation, gradually became normal brown in appearance, and the icteric index dropped from 100 to 60. Biliary drainage averaged 100 cc. per day, although the bile was quite viscid at first and very small in quantity; however, with

FIGURE 2.

This film, taken five hours after the injection of Hippuran solution, shows complete disappearance of the opaque material. None of the opaque solution is visible in the intestinal tract. There is air in the duodenum.

of the liver. The liver was greatly enlarged, especially the right lobe, which extended almost to the pelvic brim. Furthermore, omentum adherent to the gall-bladder fossa was released without difficulty, part of the inferior surface of the liver and the first portion of duodenum being brought clearly into view. A bluish discoloration of the biliary duct was readily recognized, and it was evident that the hepatic duct extending 3 cm. downward from the liver was firmly attached at a right angle with the second portion of duodenum. The hepatic duct was then aspirated with a needle and syringe, and clear bile obtained. Further inspection revealed that the hepatic duct was under tension and its walls moderately thick, and that throughout its length—from the inferior surface of the liver to the junction of the duodenum—its width was about 9 mm. Two linen traction sutures were inserted in the wall of the hepatic duct (about 3 mm. apart), and the duct opened through a longitudinal incision. Bile flowed freely, and many small inspissated particles of bile were extracted. Exploration of the duct with a probe, however, revealed that the biliary duodenal stoma was occluded and did not allow the probe to enter the duodenum. The incision of the hepatic duct was then extended through the stoma and into the duodenum, the stoma being thus enlarged. A T tube was then inserted, connecting the hepatic duct with the duodenum. Several interrupted linen sutures were used to approximate the incision and reinforced with a portion of omentum sutured with No. 00 plain catgut. A cigarette drain was inserted

FIGURE 3.

This film shows the horizontal part of the T tube in the biliary duodenal channel; the tube broke at time of removal sixteen weeks after operation. The oval area in the tube indicates where the long arm was cemented.

the administration of bile salts and iron, a definite improvement was noted in the specific gravity of the bile, and the patient regained considerable strength. She was discharged from the hospital on February 6, 16 days after operation. The total hospital stay was 20 days.

At home, temporary clamping of the T tube did not cause any discomfort, and 6 weeks after the operation the tube was finally left clamped at all times. This caused no pain or discomfort, and the stools remained brown. The patient ate about everything without any complaints. On April 21 (13 weeks postoperatively), roentgenographic and fluoroscopic examinations were made by Dr. Max Ritvo (Figs. 1 and 2).

On May 20 (16 weeks postoperatively), under nitrous oxide and oxygen anesthesia, the T tube was removed. In the process of extraction, the long arm of the tube broke off, leaving the T portion of tube in situ (Fig. 3). For a week, bile drained through the skin opening but gradually decreased, and the wound closed 14 days after this mishap. There was no change in the patient's con-

FIGURE 4.

This film, taken four and a half years later, shows absence of tube and depicts liver radicles and duodenum filled with air.

dition, and her stools continued to be brown. She had no digestive disturbances and regained much of her former weight.

X-ray films were then taken at intervals from 6 months to 1 year, and on each occasion the tube was found to be snugly in its original position. On February 7, 1942, however, the tube was no longer present (Fig. 4), and it was evident that the patient had unconsciously expelled the tube. From this, it can safely be said that the tube was in its original place for at least 4½ years. Throughout this period, the patient experienced no untoward symptoms, and for the last year had been working in a laundry.

On her last visit, February 7, she was feeling very well and had no complaints except a sense of fullness in the upper abdomen, especially after a large meal. The stools had been brown, and her weight had remained at 140 pounds. There was no jaundice, the abdominal incision was well healed, and the liver was smooth, 3 fingerbreadths below the costal margin.

DISCUSSION

This case illustrates several interesting points. The first, of course, concerns the reliability of the sidetracking operation of choledochoduodenostomy in stricture of the common duct.¹⁻⁴ That it is not always a successful procedure is well substantiated by men of experience.^{5,6} Others, dissatisfied with

the unsatisfactory results, have resorted to intubation.^{7,8} The varied opinions clearly indicate that these difficult cases are sometimes prone to failure, regardless of procedure. Unquestionably, a prognosis is most difficult to make in such cases.⁹

The second point of interest is that in this case the horizontal part of the T tube broke off at the time of removal, sixteen weeks after its insertion to relieve obstruction following choledochoduodenostomy. Whether this incident was a piece of good fortune is difficult to say. The fact remains that the broken-off horizontal part of the tube remained within the biliary duodenal channel for four and a half years without causing the usual complications of cholangitis and obstruction. Even after the expulsion of the tube, the biliary duodenal communication continued to function very well, although, of course, it is rather soon to venture any prognosis.

This incident does not appear to be the first to be reported. Fedoroff¹⁰ had a similar experience. In his case, the horizontal portion, which broke off at time of removal, was 6 cm. long, and remained within the biliary channel also for four and a half years. When removed, it was found to be covered with *Gallensand*. In Bowen's¹¹ case, it was not the horizontal portion that broke off but the end of a No. 20 Fr. catheter that had been inserted in the common duct; it was 3.8 cm. long and remained in situ for four years.

Possibly the construction of the tubes has some connection with these unusual accidents. Bowen¹¹ insists on the use of a well-made new tube and states that the tubing used should be easily visualized roentgenographically. In the case presented above, the long portion of the T tube was cemented to the short, and for this reason I am fairly well convinced that the construction and, perhaps, the age of the tube were in some measure responsible. Since this mishap, whenever the occasion arose to use a T tube, I have made sure that it was a single piece and never used before.

The final point of interest is that unintentional intubation resulted and the tube was retained for four and a half years without the usual complications. Rubber tubes within the biliary channel have been known to be retained for prolonged periods, even up to many years. The longest recorded period is twelve years¹²; the interior of the tube became encrusted with bile-pigment debris, which obstructed it. Lahey¹³ cites a case in which he removed from the common duct a tube that had functioned well for seven years and replaced it with another. At the time of his report, the second tube was still functioning satisfactorily. Behrend¹⁴ reports a case in which a straight tube

was inserted and the common duct repaired over it for reconstruction of the duct. When the tube was removed six years later, it was encrusted with bile salts. Hunt¹⁵ likewise reports a case in which a tube remained in the hepaticoduodenostomy stoma five months and ten days. He also mentions the fact that he saw an autopsy specimen in which such a tube had remained in place for eight years. Colp,⁷ in presenting his intubation method, refers to a case reported by Judd in which the tube remained in place for four years before it caused cholangitis.

I am fully aware that there are just as many interesting cases in the literature that I was unable to ferret for the simple reason that most of the cases in which a rubber tube was retained for a prolonged period have been solitary experiences and casually mentioned by the authors.

SUMMARY

Choledochoduodenostomy is occasionally prone to failure and fraught with serious complications and experiences.

A case is presented in which the horizontal part of a T tube broke off at the time of removal and became an indwelling rubber tube. It was retained within the biliary duodenal anastomosis without any complications for four and a half years.

In such operations, the use of a new T tube, constructed in one single piece, is recommended.

THE CLINICAL APPLICATION OF GASTROSCOPY*

CHARLES W. MCCLURE, M.D.,† AND I. R. JANKELSON, M.D.‡

BOSTON

THE semiflexible gastroscope was introduced ten years ago; as a result, gastroscopy became a relatively simple technical procedure. In the hands of an experienced examiner, it has proved to be a safe method of visualization of the gastric mucosa. Illustrating its increasing popularity is the fact that about four hundred and fifty semiflexible gastroscopes are now in use in this country. Most of these are of German make, but an American-made gastroscope has recently been introduced, and its satisfactory performance is vouched for by Schindler and others who have used it.

The proper evaluation of a new method of diagnosis at best takes time and the collective efforts of the medical profession. Such efforts include those of the enthusiastic pioneer and specialist,

who can compare the objective findings by a new technic with those of the older and well-established methods. However, the clinical status of a new procedure is ultimately decided by the rank and file of the profession, who learn from experience whether this method helps them in their medical practice. These observations furnish the plan that has governed our investigation of the clinical value of gastroscopy. This investigation was incident to the search for methods to increase our diagnostic acumen and persistently carried on in the Gastrointestinal Clinic of the Out-Patient Department of the Boston City Hospital. So far, we have performed over 1500 gastroscopies on patients for whose clinical diagnosis we were responsible. Thus, we have been familiar with their entire clinical record, including x-ray and other special findings. It is on the basis of these observations that we present our conclusions concerning the clinical value of gastroscopy.

In the evaluation of gastroscopy as a method for objectively demonstrating intragastric disease,

it is well to compare its relation to roentgenology of the stomach. The two diagnostic procedures are complementary, and are neither competitive nor antagonistic. With the judicious use of both, the error in gastric diagnosis can be reduced considerably.

In our clinical study of the patient, we first obtain a careful history and make a complete physical examination and indicated laboratory tests. Barium x-ray observations are next made for general orientation of digestive-tract disturbances and is an aid in excluding conditions that may contraindicate gastroscopy. After these examinations, the use of gastroscopy is given consideration for two reasons: in the presence of a gastric lesion demonstrated by x-ray study, direct inspection through the gastroscope may furnish evidence enabling a much more exact differential diagnosis; and gastroscopic inspection may disclose an intragastric lesion that the x-ray examination failed to demonstrate. These practical applications of gastroscopy will be clarified by a description of its use in four intragastric lesions. Lack of space precludes the discussion of fissure, superficial ulceration, hemorrhagic areas, diverticulum, petechiae, sarcoma, lymphoblastoma and gumma, or of observations on postoperative cases.

Of the four important intragastric lesions, chronic gastritis is by far the most frequent. The incidence of chronic gastritis is given as 42 to 44 per cent of all cases examined (Schindler,¹ Carey² and McClure, Sweetsir and Jankelson³). In a previous communication,⁴ however, we have emphasized that, in approximately 50 per cent of the cases, the gastritis is secondary either to another intragastric or to extragastric disease. By making his statement, we do not choose to commit ourselves regarding whether a chronic gastritis precedes an ulcer or cancer of the stomach or is the result of a pre-existing lesion. This is another chapter whose discussion would lead us far astray from the original purpose of this contribution. What we imply with the term secondary chronic gastritis is the presence of other lesions within the stomach or elsewhere in the body, frequently associated with inflammatory or noninflammatory changes in the gastric mucosa.

Chronic gastritis may be hypertrophic, atrophic, superficial or mixed, and its distribution may be localized or diffuse. In its clinical course, it may simulate a peptic ulcer or be mistakenly diagnosed as a gastric neurosis. Although the clinical diagnosis of chronic gastritis may be suspected, it cannot be made with certainty, and the different types cannot be recognized. The changes in gastric secretions are not diagnostic, and the demonstration

of an excess of mucus in the gastric contents, as well as the presence of leukocytes, is not conclusive evidence. Generally, the clinical laboratory gives indefinite information in this disease. The atrophic and superficial types cannot be demonstrated by either fluoroscopy or x-ray study. The frequently seen large rugae within the stomach are not necessarily due to hypertrophic gastritis (Berg⁵ and Ansprenger and Kirklin⁶). Thus, the roentgen rays are not diagnostic. The only clinical method for ascertaining the presence, type and distribution of gastritis is gastroscopy. The use of gastroscopy for this purpose has impressed us with the fact that minor variations in the appearance of the gastric mucosa as seen through the gastroscope should not be emphasized and that only gross variations from normal are of diagnostic significance. More recently, Swalm and Morrison,⁷ in a gastroscopic study accompanied by biopsies and microscopic examinations of specimens of the gastric mucosa, came to the same conclusions. Their microscopic studies showed a high percentage of verification of the gross picture of chronic gastritis in the cases in which the changes were marked, whereas in the minor variations the error was much greater. Thus, one may say that the diagnosis of chronic gastritis is largely made on the basis of gastroscopic findings. Very similarly, lesions that often accompany a chronic gastritis, such as fissures, submucous hemorrhages, petechiae and small inflammatory polyps, can be recognized clinically only with the aid of a gastroscope. Without it, these lesions may be suspected, but a definite diagnosis is impossible.

The second lesion, peptic ulcer, may be diagnosed clinically if a typical history is obtained. However, an ulcerative gastritis, an ulcerating carcinoma of the stomach or multiple fissures of the stomach may mimic a peptic ulcer to an extent that a differentiation becomes clinically impossible. Moreover, the localization of an ulcer is impossible on the basis of history, physical examination or clinical laboratory data. We need not discuss the necessity of differentiating a gastric ulcer from a duodenal one. Suffice it to say that the former is potentially a cancer, whereas the latter almost never becomes carcinomatous. Hence, every clinical diagnosis of peptic ulcer or a serious suspicion of one requires verification and localization with the aid of a barium meal and fluoroscopic and roentgenographic studies. Thus, the majority of ulcers are located, their sizes and depths determined, their progress evaluated, most of the complications discovered, and the indications for surgery confirmed. However, many ulcers within the stomach are so situated or so superficial that

they cannot be visualized by roentgen rays; frequently, these can be seen by gastroscopy. Furthermore, one cannot determine whether some ulcerative lesions are benign or malignant on roentgenologic evidence, even if the examination is repeated at frequent intervals. However, the gastroscope frequently contributes information that permits the proper classification of such lesions.⁸ In the gastroscopic examination, not only the appearance of the ulcer but also the character of the gastric mucosa of the rest of the stomach may give evidence of the character of the lesion. For example, in the vast majority of benign ulcers, the gastric mucosa appears normal or hypertrophic changes are present, in carcinoma, almost invariably, the entire gastric mucosa is atrophic, whereas in an ulcer that has undergone malignant degeneration only the adjoining mucosa is atrophic.⁹

Although healing of an ulcer can be demonstrated by roentgen rays, at times this evidence is misleading because the niche may appear smaller or less penetrating as a result of exudate accumulated on its base and not due to repair. Such a condition is demonstrable by gastroscopy, which in our experience has proved itself superior to roentgen rays in following the progress of the healing. With the aid of preoperative and postoperative gastroscopy, one makes observations pointing to a major factor in the prevention of the late postoperative gastritis that may accompany peptic ulcer. Our studies indicate that the ultimate results in ulcer surgery are better if the operation is performed at a time when an accompanying gastritis is properly controlled than when it is active. On the other hand, a gastric ulcer not visualized on gastroscopy may occasionally be demonstrated by radiography; therefore, the inability to see an ulcer by gastroscopy does not exclude its presence.¹⁰ Thus, the use of both methods is strongly advocated to reduce the error of diagnosis.

The diagnosis of the third lesion, carcinoma, is usually easy in advanced cases. The appearance of the patient, rapid loss of weight, epigastric distress and anorexia make one suspect it whether or not a palpable mass is present in the epigastrium. Almost invariably, the tumor mass can be located and its extent determined roentgenologically. In other words, only very rarely do the roentgen rays fail to visualize an irregular, moth-eaten deformity of the stomach. However, in a few cases of extensive carcinoma of the stomach, usually involving the posterior wall or the cardiac end, the routine x-ray examination is either inconclusive or negative. In such cases, gastroscopy is indicated and often solves the diagnostic problem. In our experience, gastroscopy is of great help in determining the extent of involvement of the stom-

ach. On the other hand, gastroscopy gives no information concerning regional lymph-node involvement or distal metastases and therefore does not in itself settle the question of operability. Obviously, resectability can be determined clinically only by employment of all methods of examination at one's disposal, including peritoneoscopy.

The early diagnosis of cancer of the stomach is often difficult. The condition is only suspected clinically, and because of the value of an early diagnosis all methods of clinical investigation should be utilized. Roentgen rays and gastroscopy are the two major methods of arriving at an objective diagnosis. If the lesion involves either gastric orifice, the x-ray evidence is usually conclusive. But when the early carcinomatous lesion is away from the cardiac or pyloric orifice, gastroscopy, at least in our experience, frequently becomes essential in the making of a definite diagnosis.

The fourth group of lesions, benign tumors, usually comprise polyps and leiomyomas. The former originate from the mucosa, protrude into the cavity of the stomach, vary in size from a pea to a walnut, and may be single or multiple. A generalized polyposis of the stomach also occurs. The seriousness of polyps lies in the fact that they may ulcerate and bleed and that more than 40 per cent undergo malignant degeneration. Although the larger ones can be demonstrated roentgenologically, the smaller ones may escape detection; thus the radiographic demonstration of gastric polyps is uncertain. Gastroscopically, however, the polyps can be seen, their number determined, their size estimated, ulcerations or bleeding points demonstrated and areas of early malignant degeneration often observed.

The leiomyomas spring from the muscle layers of the stomach, usually in the cardiac end, and may appear as submucosal or subserosal tumors, covered with normal mucous membrane. They too may bleed when they ulcerate and show a tendency to sarcomatous degeneration. Since these lesions are covered by normal mucosa, their character cannot be determined by gastroscopy. Particularly, the subserosal ones, cannot be seen through the gastroscope. The roentgen rays, however, most frequently give information of their location, size and character. These observations emphasize the desirability of both methods in gastric diagnosis.

Whereas other methods, such as roentgenology, give objective information not only about the stomach but also about the adjacent organs, such as the esophagus and duodenum, the scope of gastroscopy is much more limited. Only the mucosa of the stomach can be seen by this method of examination. Moreover, even within the gastric cav-

ity, certain areas may not be visualized and thus a localized lesion may be overlooked on gastroscopy. On the other hand, not only is a lesion located through this instrument but also much information about its character, type, extent and distribution is obtained. Primarily, the gastroscopy gives information about the gross pathologic changes.

Gastroscopy has limitations. In carcinoma, the walls of the stomach may become rigidly infiltrated and lose their distensibility, visualization through the gastroscope being prevented. Although lesions involving the entire gastric mucosa, such as diffuse gastritis, lymphoblastoma and polyposis, can hardly be overlooked on gastroscopy, localized lesions—an ulcer or a single polyp—can be missed on a single examination. The dependability of this procedure in the final analysis depends largely on the experience of the examiner. Besides these limitations, there are contraindications to gastroscopy, which should be scrupulously observed, lest unnecessary accidents be encountered and serious injuries produced to the patient. Since we¹¹ have already listed such contraindications to and limitations of gastroscopy, the reader is referred to this previous publication.

* * *

Roentgenology and gastroscopy are complementary methods of diagnosis, and thus are neither competitive nor antagonistic. In other words gastroscopy is an additional method of arriving at an anatomic diagnosis in diseases of the stomach. As such, it does not exclude any other form of examination. In our experience, it has proved to

be a useful procedure, which in many cases has given evidence not obtained by any other method of examination and in others has confirmed evidence otherwise recognized or suspected. Judiciously used, gastroscopy has enlarged the scope of diagnostic acumen. For example, it has rehabilitated the concept of chronic gastritis. It has proved to be a useful procedure in the diagnosis of gastric ulcer and cancer, in preoperative and postoperative observations of the gastric mucosa and in the differential diagnosis of gastric ulcer and cancer. In our opinion, gastroscopy furnishes objective findings whose clinical significance should be established in relation to the history, physical examination, laboratory findings, gastrointestinal roentgen ray studies and all other special studies indicated.

MEDICAL PROGRESS

STILBESTROL

JOHN ROCK, M.D.,* AND MIRIAM F. MENKIN, M.A.†

BOSTON

"STILBOESTROL" was the name given by Dodds, Goldberg, Lawson and Robinson¹ in 1938 to the compound, 4:4'-dihydroxystilbene, which they prepared from an extract of the oil of aniseed, and which they discovered to be estrogenic. The diethyl derivative (4:4'-dihydroxy- $\alpha\beta$ -diethylstilbene) of this synthesized vegetable hydrocarbon, however, has been found to be so much stronger in estrogenic effect as to make stilbestrol itself clinically unimportant.

GENERAL CONSIDERATIONS

Nature of Drug

The precise Council on Pharmacy and Chemistry of the American Medical Association² prefers to limit the name "stilbestrol" to Dodds's original simpler and weaker estrogen (4:4'-dihydroxystilbene) and uses the rather cumbersome descriptive name "diethylstilbestrol" for the more potent derivative now in such general use as practically to exclude the weak mother substance. In this paper, stilbestrol is employed to designate the drug in common use, 4:4'-dihydroxy- $\alpha\beta$ -diethylstilbene.

Whether used in tablets, in suspensions or in solutions, or whether given by mouth, by injection or implantation, by way of the vagina or percutaneously, stilbestrol, although it is not a true hormone, appears to have all the clinical estrogenic power of the female sex hormone, estradiol, and its various derivatives.³⁻⁶ Whereas Greene⁶ rates 1 mg. of stilbestrol as equivalent to about 20,000 I.U. (international units), or 2 mg., of estrone when both are given parenterally, the same effect is produced by only 0.3 to 0.4 mg. of estradiol benzoate similarly administered. Stoddard and Metzger⁷ report that in the human subject 0.42 mg. of estradiol benzoate, injected intramuscularly, is equaled by 0.5 mg. of stilbestrol taken orally.

The distinct advantage of stilbestrol over estradiol, clinically the most potent of the estrogens, is thus evident. Whereas estradiol loses most of

its efficacy when taken orally, stilbestrol is almost as potent by mouth as by injection.

Cost

A second decided advantage of stilbestrol over estradiol is its lower cost. On the basis of human assay, the result produced by the intramuscular injection of 0.42 mg. of estradiol benzoate, priced at \$1.07, may be duplicated by the oral consumption of 0.5 mg. of stilbestrol, costing less than 2 cents.⁷

Pharmaceutical Forms

The drug is dispensed in small tablets, some of which are enteric coated, as well as in capsules and suppositories. Soon, no doubt, it will be obtainable in solutions or suspensions for percutaneous use, as well as in pellets that can be implanted, since these forms have been successfully employed in clinical experimentation.^{8, 9} It is questionable, however, whether these will ever be of great value, since stilbestrol is so effective by mouth.

Dosage

The effective dose of stilbestrol varies considerably because patients have widely different susceptibilities, both to desired and undesired results, and because among the many disorders that it may relieve, some are easily affected, whereas others are very resistant. Since the drug may have unpleasant sequelae, as mentioned below, it is wise to begin treatment with as little as 0.1 mg. by mouth daily. If well tolerated, this may be increased even up to 5 mg. daily, although only occasionally is it necessary to exceed 1 mg., and only rarely, as for the suppression of lactation, is one obliged to give more than 2 mg. daily. When injected, it should be put in muscle, and then only on every third or fourth day; the gluteus medius on alternate sides is very suitable.

Utilization

Stilbestrol is effectively absorbed from both the intestines and the muscles but is not utilized in the same degree from these two sources. On the basis of analyses made on 3 menopausal patients, von Haam et al.¹⁰ estimated that 10 to 30 per cent of a single large dose of injected stilbestrol was ex-

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress: Annual, Vol. III, 1942* (Springfield, Illinois: Charles C Thomas Company, 1942. \$5.00).

*Instructor in gynecology, Harvard Medical School; visiting surgeon, Free Hospital for Women.

†Research associate, Free Hospital for Women.

reted in the urine and feces during the first ten days after its administration. Zondek¹¹ reported that one fourth of the amount injected into infantile rats could be recovered from the excreta. He also found that, forty-eight hours after injection, stilbestrol could be recovered by extraction only from that half of the animal in which it had been injected. There is therefore "storage" at the site of injection. The limits of storage after implantation of pellets were suggested by Forbes,¹² who stated that 90 per cent was absorbed in the rat in fifty-one days.

Toxicity

The dosage is properly limited to that which gives the desired effect, but also by possible gastrointestinal disturbances, and occasionally by less common sequelae, such as those noted in the literature by Morrell.¹³ These include headache, drowsiness, vertigo and dermatoses. Von Haam et al.¹⁰ mention excessively increased libido. We have not been informed of anything approaching this by our patients; nor indeed, except rarely, have we found it to increase sex drive at all. Physicians were made unduly apprehensive of the toxicity of stilbestrol by some early investigators, who, accustomed to the mild estrogenic effects of some of the hormones, used what proved to be unnecessarily large doses. The long delay in approval by the Food and Drug Administration, while it very properly gathered large numbers of reassuring reports,^{6, 13-16} contributed to the uncertainty among clinicians.

Our experience regarding toxic reactions is much the same as those cited. We find that such symptoms as nausea, vomiting, headache and malaise were encountered in 31 of 199 patients (15.6 per cent) treated for various complaints, chief among which were menopausal symptoms and menstrual disorders.* Toxicity depends on individual sensitivity as well as on dosage. The menopausal patients appear to be less susceptible than those treated for menstrual disorders. Toxic symptoms were reported in only 12.4 per cent of the former, as compared with 23.1 per cent of the latter.† Pregnant or lactating women are said to tolerate tremendous amounts^{8, 11, 17, 18}. Zondek and Bromberg¹⁰ mention a patient who could take one hundred and seventy times as much stilbestrol when pregnant as when not pregnant; they concluded that there was a detoxication of the material during pregnancy. Toxic reactions are not confined to stilbestrol, but may be elicited also by overdosage

with any of the hormonal estrogens.⁶ There seems to be no evidence of serious liver, kidney or bone-marrow damage, such as was feared following the earliest reports,^{13-16, 20} when unsuspectingly excessive doses were used. Transient nausea is the commonest of the infrequent objections to the drug. We have satisfactorily avoided this by instructions to take the tablet at bedtime, because the disagreeable symptoms usually follow only a few hours after ingestion. Abarbanel and Klein⁸ find that bile salts or acid preparations help in preventing these effects. Others¹ believe that the enteric-coated pill is less troublesome.

Finch²² regards these untoward symptoms as an allergic response and reports desensitization to the drug by frequent medication, beginning with a low dosage and gradually increasing this until the therapeutic level is reached. An allergic reaction to stilbestrol had previously been noted by Baird.²³

Hamblen²⁴ expresses perhaps the greatest danger in the use of nonhormonal estrogens. "Being orally active, cheap and highly potent, uncritical use of them by physicians and self medication with them by patients would add, doubtlessly, to an already widespread contraphysiologic and empiric estrogenic therapy."

Carcinogenic Effect

Much loose thinking has prevailed regarding the carcinogenic properties of the estrogens, among the most potent of which one must place stilbestrol. Since its effect on the uterus and breast is similar to that produced by various natural estrogens, it seems more than likely that its potentiality to develop cancer is the same. But for cancer to develop, the unknown cancer factor is generally considered essential. On the other hand, once the cancer factor is activated by the intrinsic growth potential or by artificial growth stimulus, such as Gardner et al.²⁵ gave in the form of estrogen to male mice of a cancer strain, the tumor may then progress, even if the artificial stimulus is discontinued. Removal of an endogenous agent sometimes effectively halts the growth. This has been seen after castration in some cases of metastatic cancer of the breast, and also of cancer of the prostate. The great majority of experimental efforts to initiate cancer in various species, even including the monkey, have failed. Zondek¹¹ has mentioned several investigative attempts, some apparently successful, and also reported his failure to induce cancer by giving tremendous doses of estrogen over many months to members of his strain of rats, among 5000 of which no spontaneous cancer had ever been found. He recorded Engle and Smith's failure to produce

*This study was carried on at the Free Hospital for Women, Brookline, Massachusetts, with material generously supplied by the Winthrop Chemical Company Incorporated, New York City.

†The previously quoted figure 15.6 per cent refers to the incidence of toxic symptoms in a group of 199 cases which also included other conditions such as

cancer in 4 macaques and also Zuckerman's inability to cause cancer in monkeys by large doses of estrone over long periods. Zuckerman treated monkeys for a year with a total of 365,000 I.U. of estrone. Because 2 women, both of whom had received 50,000 I.U. of estradiol benzoate daily for twenty-four days, or a total of 1,200,000 I.U., showed no carcinoma, Zondek concluded that even extremely large doses of hormone did not cause carcinomatous changes of the uterus. He believes that large doses may even protect against the initiation of cancer because of the consequent inhibition of the growth effect of the anterior pituitary gland, as well as by the resultant hormonal castration. In 195 patients who received appreciable amounts, we have seen no cancer develop during the exhibition of stilbestrol or soon after its consumption. Because of the nature of estrogen metabolism, long-delayed effects of its use are not to be apprehended. This does not mean that cancer need not be kept constantly in mind, for it can develop in any female at any age. However, we do not subscribe to the notion that any estrogen per se is carcinogenic.

CLINICAL USE

Primary Amenorrhea

Stilbestrol, like the natural estrogens, is unpredictable as a precipitant of bleeding in cases of primary amenorrhea but, if given for two or more weeks, usually produces flow, either during the treatment or as a withdrawal phenomenon. The dose need not exceed 2 mg. daily; Palmer²⁶ used seven daily doses of 1 mg. each, followed by seven daily doses of 5 mg. Doses larger than 2 mg. may elicit unpleasant nausea or tenderness of the breasts. In susceptible persons, however, toxic symptoms may follow the exhibition of only 0.1 mg. daily. If a clinical *tour de force* is sought because of the temporary psychologic "lift" that a period of flow gives the defective girl, it may be more surely obtained by the simultaneous ingestion of 2 mg. of stilbestrol and the intramuscular injection of 5 to 10 mg. of progesterone on five successive days.

Secondary Amenorrhea

In the girl or woman whose germinal epithelium is active, but who has merely stopped maturing follicles, stilbestrol is much more useful. One milligram daily by mouth for fourteen to twenty-one days is almost certain to be followed, within four to ten days, by a flow that satisfies the patient. In a very few cases, a second spontaneous flow follows some weeks after treatment. If a succeeding series of treatments is started at the time of the bleeding, the flow is usually repeated. This may be

kept up for months, but the likelihood of spontaneous recovery of the ability to ovulate is not thereby enhanced; we have observed, however, that it is not always destroyed.

Aperiodomenorrhea (Immeasurable or Anovulatory Menstruation, Uterine Dysfunction)

When flowing is irregular in incidence or prolonged, and sometimes when it is profuse, it may be brought to a semblance of normality again by repeated cyclic series of stilbestrol treatments, consisting of 0.5 to 1.5 mg. daily for arbitrarily selected periods of fourteen to twenty-one days. Succeeding periods of treatment are started with or soon after each period of flowing.

Menopausal Symptoms Incident to Normal or Artificial Climacteric

The greatest value of stilbestrol is in the treatment of these conditions. Initial dosage is properly about 1 mg. daily. When comparative comfort has been re-established, the dose should be diminished to the individually critical level, which may seem ridiculously low; occasionally, it can be increased without causing toxic symptoms. Natural remissions in the first ten years of the normal menopause are not infrequent, and at such times, medication should be reduced or omitted. Intermittent administration of any estrogen is necessary to relieve the anterior pituitary gland of undue inhibitory influences. There is as yet no reason to suppose that the carefully graded use of any estrogen during the menopause merely postpones the evil day when the unpleasant subjective symptoms must be suffered before stabilization is accomplished. Rather, it seems that final comfort without medication can be gradually attained by the use of smaller and smaller doses of an estrogen; and stilbestrol is a good one.

Of great significance during and after the menopause is the fact that stilbestrol stimulates proliferation of the endometrium and establishes therein the potentiality to bleed, and that this potentiality may be activated during treatment and will surely express itself after cessation of the drug, if it has been used for several weeks. This phenomenon is important mainly because it may not disturb the unwary clinician as much as it does the apprehensive patient. The first bleeding from cancer of any part of the uterus must not be overlooked. Careful examination and continued close observation for long periods after omission of the drug are essential.

Suppression of Lactation

We have not used stilbestrol to inhibit lactation. Davis and Boynton¹⁵ report that if treatment with 5 mg. for eight to ten days is started promptly on

delivery, no engorgement occurs. If, on the other hand, the drug is withheld until after lactation is established, they state that the engorgement of weaning, although it does take place, is usually slight. Abarbanel and Klein⁸ found that stilbestrol in doses up to 500 mg. did not affect established lactation in the nursing woman. Mendel, Goldman, and Caire²⁷ noted primary suppression of lactation in 98 per cent of 55 patients. Many other workers^{8, 17, 18} present similar results, and all mention the extreme infrequency of any unpleasant symptoms, even though such large doses are given as would certainly be toxic to the nonpuerperal patient.¹⁹ Abarbanel and Klein⁸ gave doses ranging from 250 mg. a day to 1500 mg. a week to pregnant and puerperal patients, and recorded no toxic effects except occasional dizziness.

Dysmenorrhea

For dysmenorrhea, a very common gynecologic disorder, estrogens, stilbestrol among them, have a very limited field, because to relieve the pain they must prevent ovulation. Thus, to upset what is frequently a delicately balanced mechanism in any girl is usually too high a price to pay. Sturgis²⁸ is right when he says that if 1 mg. of stilbestrol is given daily for twenty days, beginning a full week before the expected time of ovulation, the succeeding period of flow will be painless. He finds, furthermore, that the omission of treatment in the succeeding cycle permits the re-establishment of ovulation. Therefore, the procedure may occasionally be justified in the rare patient who apprehends that pain will materially interfere with some important performance—artistic, athletic, social or academic. Frequent or prolonged use of this method might seriously upset the endocrine balance that is necessary for normal cyclic ovulation.

Senile Vaginitis

In postmenopausal vaginitis, suppositories containing 0.5 to 1 mg. of the drug used daily for several weeks will rejuvenate the vaginal epithelium and re-establish its high resistance to the commoner bacterial and fungoid irritants. Davis and Boynton¹⁵ recommend the use of a 0.5 mg. suppository each evening for six to eight weeks; we have noted alleviation of the condition in less time. Abarbanel and Klein⁸ effectively used a stilbestrol ointment for this purpose, and also suggested stilbestrol in suppositories for gonorrheal vulvovaginitis in children, a condition with which we have had no experience.

Pruritus Vulvae

As an adjuvant in the relief of vulvar itch, which is often very distressful, stilbestrol by mouth in

doses of 0.5 or 1 mg. daily, or by inunction, as reported by Abarbanel and Klein,⁸ by Wharton²⁹ and by Lubow,³⁰ may be very helpful, but other measures should also be taken. The urine must be sugar free. The application of 2 per cent boric acid helps to eradicate the almost constant bacterial dermatitis, and painting with gentian violet usually removes the commonly found fungus.

As already mentioned in connection with the menopause, stilbestrol may also evoke bleeding in the aged if given for several consecutive weeks. When it does so, the treatment must be stopped, and any recurrence should be regarded as indicating cancer until thorough search by curet and biopsy reveals no such growth.

* * *

Stilbestrol, a potent synthetic estrogen, is marketed in various forms, since it is effective orally, intramuscularly or percutaneously, and bids fair to supplant the natural estrogens in therapeutics. The standard daily dose is considered to be 0.1 to 1 mg., although some patients profitably take as much as 5 mg. Overdosage or undue susceptibility is associated with nausea and occasionally with various other symptoms of mild toxicity, but there is no evidence that the drug is dangerous. It has been reported that desensitization is possible by the use of gradually increasing doses. During pregnancy and lactation, tolerance is tremendously raised.

Like other estrogens, stilbestrol seems not to be carcinogenic *per se*, but it does cause proliferation in the epithelium of the reproductive system.

Its greatest usefulness is in the treatment of menopausal symptoms and in the production of flow in the amenorrheic patient. It may occasionally be used for the relief of dysmenorrhea, provided that treatment is started at least one week before ovulation time, so that follicular rupture is prevented.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 28411

PRESENTATION OF CASE

A fifty-two-year-old married woman was admitted to the hospital because of pain in the chest.

Ten months prior to admission, the patient noticed transient pain in the chest beneath the left breast. This was not severe but was worse on inspiration. Soon after this, she developed exertional dyspnea and often wheezed. She was treated by her physician for a "heart condition," and digitalis was administered. Following this, all symptoms were relieved. Six weeks before entry, the patient developed a little pain under the upper portion of the left shoulder blade and occasional pains in the left shoulder. At about this time, she noticed that the left upper chest seemed "full" and that the veins over the chest were prominent. She believed that she had lost a little weight.

The family and past histories were irrelevant. A brother had died of cancer of the rectum.

Physical examination revealed a nervous, well-developed and well-nourished woman in no distress. The pupils were equal in size. Examination of the heart and right lung was negative. The left upper chest seemed fuller than the right. The veins over this side appeared prominent. The amplitude of inspiratory and particularly expiratory movements was reduced. The anterior and posterior aspects of the upper left chest were flat to percussion. Tactile fremitus and breath sounds were diminished above the fifth rib anteriorly and the eighth rib posteriorly. There was a fullness of the left supraclavicular fossa, which seemed to extend beneath the clavicle. The left hand was warm and dry; the right was cool and wet. Abdominal examination was negative.

The blood pressure in the left arm was 152 systolic, 82 diastolic, and in the right arm, 138 systolic, 80 diastolic. The temperature was 98.1°F., the pulse 78, and the respirations 20.

Examination of the blood revealed a hemoglobin of 14.5 gm. and a white-cell count of 8100 with 81 per cent polymorphonuclears. The urine was acid in reaction and had a specific gravity of 1.022; the sediment contained 22 white cells and 7 epithelial cells per high-power field. An electrocardiogram demonstrated a normal sinus rhythm

of 65. There was a tendency toward right-axis deviation, but the record was within the normal range. T₁ was flat to very slightly diphasic; T₄ was flat to very slightly inverted. The blood Hinton test was negative.

An x-ray film of the chest revealed a dense homogeneous mass that filled the left pleural cavity from the apex to the eleventh rib (Fig. 1). The lower margin of the mass was lobulated. The mediastinum and heart were displaced markedly to the right. The lung between the lower limits of the mass and the left diaphragm appeared to be bright, probably owing to emphysema. The right lung field was clear, and there was an azygos lobe. There was no definite evidence of erosion of the ribs or enlargement of the intervertebral foramina. The patient was operated on fourteen days after admission.

DIFFERENTIAL DIAGNOSIS

DR. HELEN PITTMAN: May we see the x-ray films?

DR. GEORGE W. HOLMES: Whatever this process is, it has advanced beyond the stage where the radiologist can make a complete diagnosis. The process is homogeneous throughout on the routine film. On a film taken with a Bucky diaphragm, this finding was confirmed. Consolidation with cavity formation might look like this, on the first film, but not like that, on the second; so we can be fairly certain that the lesion had a fairly homogeneous density throughout. The heart and mediastinal contents are displaced away from the lesion. That is evidence of some space-filling lesion, such as fluid or tumor, rather than collapse. The fact that the lower part of the lung field is clear is against a large accumulation of fluid in the pleural space. The fact that it bulges might be interpreted as due to fluid or tumor. The absence of erosion of the ribs or bodies of the vertebrae is against a tumor arising from the sympathetic chains or the spinal nerve roots,—the neurofibroma group,—but it is not against a primary lung tumor. The fact that the other lung is clear is against a tuberculous lesion. I think the evidence we have here rather points toward neoplasm; whether it was primary or secondary, we have no definite evidence.

DR. PITTMAN: We are obviously faced here with a tumor of the mediastinum, and how much farther than that I can go I am not at all sure. I can do a certain amount of reasoning and a larger amount of guesswork, and end up with "tumor of the mediastinum, type to be determined later on."

We have a fifty-two-year-old woman, who was not sick, who may have lost weight, but who was still well nourished, and who had no fever or leukocytosis. Ten months before entry, she began to have pain. Then she was well for eight months but, by the time of entry, was having more symptoms. The only symptoms that she had had are

sympathetic system, demonstrated by the fact that her hands showed different temperatures and different degrees of moisture, and bronchial pressure, indicated by lack of aeration except at the base, where there appeared to be some emphysema.

I am not going to inflict on you a complete differential diagnosis of tumors of this region of the

FIGURE 1. *Anteroposterior Film of the Chest.*

those that I attribute to pressure. True, the pain that she had at the beginning in her left breast and the pain later in the left shoulder may have been pleural and not due to pressure. A few things here I think are a little queer. If not queer, I just do not understand them. She had a large mass in the left chest bulging above the clavicle. Vascular compression was evidenced by dilated veins, and yet the blood pressure on that side was higher than on the other side. I have no idea how or why that occurred. She also had pressure on the

body. I think there are three things to be considered.

The first one I thought of, as I read over the record and before I had seen the x-ray films, was aneurysm, and we still must consider aneurysm of the descending aorta; such lesions are relatively symptomless and likely to be silent until they have attained considerable size and are then picked up because of pressure symptoms. This holds true in this woman. On the other hand, with an aneurysm of this size, I think we should expect to find

ome evidence of erosion of the vertebral bodies r ribs. The blood Hinton test was negative, and ie had equal pupils. I do not believe we have ough evidence here to make a diagnosis of an- uryism.

Then we come to new growths in this region, nd a solid malignant tumor is a possibility. I be- eve sarcoma is far and away the commonest. This atient had a very large lesion without any evi- dence, so far as we are told, of metastatic disease. t seems hard to me to consider sarcoma as large s this with no evidence of the same disease else- where in the body, and in a woman who is not ick. Lymphoma can never be excluded. One al- ways has to mention it. Very much the same ar- gument holds as in sarcoma. The only tempera- ure report is a normal one. Again, the woman s not sick, and no mention is made of en- arged lymph nodes. It does not say that she had one, but I am assuming that that information s not intentionally left out, and that none were ound.

I have never seen an intrathoracic thyroid gland at all comparable in size with this, and I am just ot taking any stock in it. That brings us down o benign tumors of the mediastinum, which are statistically rare. I think, however, that a benign tumor fits in with the situation we have here easonably well, a very large growth with no symp- oms until it caused pressure, and in a woman who was not ill.

A dermoid is always a possibility. The Bucky film certainly shows a uniform density, but unless one can pick up a tooth or bone or something else of different density or unless there is ulceration into the bronchus, one cannot be sure. The patient coughed up no characteristic material. I do not see that we have any right to think we are dealing with a dermoid, particularly since this woman was older than most individuals are when dermoids are found. A lipoma, which could occur in this position, must be seriously considered even though it is not seen very often. I believe fibromas also can arise in this position. They are not seen often, but again they are picked up only because of their pressure symptoms in an essentially healthy person. I have considered this mass as having arisen from the structures of the mediastinum, but I suppose there is no way of being sure it did not arise from either bronchus or lung. We have very little, however, pointing to its origin in a bronchus or the lung, so I am going to stick to the medi- astinum as the source. I am therefore left just exactly where I was in the beginning, with a large lump occupying the chest, and I do not know what it is, but I think it is extremely unlikely to be a malignant tumor. I think we have no data on

which to make a diagnosis of aneurysm and I therefore make a diagnosis of benign tumor and suggest that it might have been a lipoma.

DR. TRACY B. MALLORY: Would you expect it to have that degree of density, Dr. Holmes?

DR. HOLMES: No.

DR. MALLORY: A fibroma would fit better with what you see?

DR. HOLMES: Yes.

DR. EDWARD D. CHURCHILL: We made a diagnosis of benign mediastinal tumor. The rest of the problem was a technical and mechanical one. The first consideration, in which we very likely decided incorrectly, was the route of approach. There were two choices. The incision may be placed anterolaterally or posterolaterally. Because of the evidence that the tumor extended above the clavicle, and in anticipation of difficulty in freeing it from the subclavian artery or vein, we chose an anterolateral incision. The operative notes read as follows:

A portion of the seventh rib anteriorly was resected, and the pleural cavity opened. An enormous tumor was found, apparently completely filling the left chest. It was obvious that a wider opening of the chest was necessary. The sixth rib was divided and retracted. This did not give satisfactory exposure, and it was necessary to divide the manubrium, which was done transversely in the region of the sixth costal cartilage. This enabled a hand to be passed up and around the tumor. The lung was found displaced and compressed downward and backward, and apparently was completely atelectatic. The tumor had extended high into the left apex and was adherent to the posterior mediastinum and posterior surface of the left apex of the chest. It was freed up and gradually released. There was profuse bleeding from veins on the inner aspect of the chest wall in the apex. An attempt was made to stop hemorrhage by ligatures and suture. Several sutures were taken in the posteromedial aspect of the collapsed left upper lobe, and this in turn was sutured into the apex. During the procedure, the patient went into shock, apparently owing to blood loss. Two transfusions were given during the operation.

In order to deliver this enormous solid tumor even after making the maximum exposure by resection of ribs, it was necessary to divide the sternum transversely. I had hoped of course that the tumor was cystic and that its size could be reduced by aspiration, but that was impossible because it was a solid tumor. A tumor of this size in the chest does not have a pedicle, like a tumor of the ovary, which can be simply dealt with because, when it is delivered, the pedicle can be secured. This tumor had a broad base on the lateral aspect of the vertebral column and the heads of the ribs.

The patient died of primary hemorrhage because the blood was coming much faster than we could put it in with transfusion. This represents

an error in surgical judgment, since we could not control a situation that we had created. Whether, if I had utilized a posterolateral incision, it would have brought me nearer the lateral aspect of the vertebrae with better opportunity to control the large veins before they were cut or torn, I do not know. If I were doing it again with this experience in mind, I should certainly use a posterolateral approach.

CLINICAL DIAGNOSIS

Mediastinal tumor (? neurofibroma).

DR. PITTMAN'S DIAGNOSIS

Benign tumor of mediastinum (? lipoma).

ANATOMICAL DIAGNOSIS

Fibroma of mediastinum.

PATHOLOGICAL DISCUSSION

DR. MALLORY: From the histologic point of view, this was a fibromatous tumor, evidently very slowly growing and of long duration. It showed small areas of cystic degeneration, though not enough so that an appreciable amount of fluid could have been withdrawn and the mass significantly reduced in size. It was essentially a solid tumor. There were also large foci of xanthomatous degeneration with many cholesterol crystals. Whether it arose from the perineurial sheaths, I cannot say with certainty. It has not the obvious earmarks of perineurial fibroma, but on the other hand, there are areas that do suggest such a diagnosis. Since the majority of tumors in the mediastinum are of neural origin, that would be my guess; but I cannot prove it.

DR. CHURCHILL: There was a definite constriction ring in the tumor representing the first rib and the clavicle. It was hourglass in form where it had extended up above the first rib and had become tightly wedged in place.

DR. MALLORY: There is one discrepancy between your operative findings and the x-ray report. That is the question of air beneath the tumor. Your impression, I believe, was that the lung was entirely collapsed.

DR. CHURCHILL: Undoubtedly the lower portion of the lung contained air.

DR. RALPH ADAMS: Would you expect erosion of the ribs posteriorly in such tumors?

DR. HOLMES: Yes.

DR. CHURCHILL: That was another reason we went in anteriorly.

DR. LERMAN: Can you tell where the blood supply is coming from?

DR. CHURCHILL: Only in retrospect.

DR. JACOB LERMAN: In any type of tumor?

DR. CHURCHILL: Very often it is predictable, as, for example, with an intrathoracic goiter.

CASE 28412

PRESENTATION OF CASE

A thirty-six-year-old married woman was admitted because of pain in the chest.

Approximately three months prior to admission, the patient began to have rather severe aching and, at times, shooting pains in the left side of the chest above the breast. Often, the pain seemed to radiate down the left arm and occasionally to the spine posteriorly. The episodes varied in length from a few minutes to an hour and occasionally awakened the patient during the night. The pain was not related to exertion. During this illness, the patient suffered with infrequent dizzy headaches and was slightly dyspneic. She was able to climb only a single flight of stairs. Occasionally, the dyspnea was relieved by taking soda and belching. During this time, she raised a small amount of pale-yellow sputum without coughing. Two months before entry, x-ray treatment was administered to the chest, following which her symptoms of shortness of breath were relieved and the amount of sputum reduced.

The family history was noncontributory. When twenty-six, the patient had pneumonia, which was complicated with right-sided empyema necessitating rib resection and open drainage; Type 4 pneumococci were recovered from the pus. She made a satisfactory recovery and had no symptom related to the chest until the present trouble.

Physical examination revealed an obese woman in no acute distress. Examination of the heart and lungs was negative except for a few rales audible at the base of the right lung posteriorly. There was a slight amount of tenderness over the entire lower abdomen—the patient stated that she was menstruating.

The blood pressure was 110 systolic, 70 diastolic. The temperature was 99°F., the pulse 77, and the respirations 20.

Examination of the blood revealed a hemoglobin of 14 gm., and a white-cell count of 9500 with 73 per cent polymorphonuclears, 15 per cent lymphocytes, 6 per cent monocytes, 5 per cent eosinophils and 1 per cent basophils. A catheterized specimen of urine was acid in reaction, had a specific gravity of 1.015 and gave a ++ test for albumin; the sediment showed 20 white cells, occasional epithelial cells and many bacteria per high-power field. The blood Hinton reaction was negative. The nonprotein nitrogen was 22 mg. per 100 cc.

An x-ray film of the chest demonstrated an 8-by-5-cm. homogeneous mass attached to the right posterior margin of the trachea from the level of the clavicle downward; the mass displaced the

bringing out the outline of the tumor. Here you see the displaced esophagus and trachea. The arch of the aorta is here. The lateral view does not help us.

DR. ADAMS: Does the displacement of the

FIGURE 1 Anteroposterior Film of the Chest.

trachea and esophagus to the left (Fig. 1). The displacement of the esophagus appeared to be due to pressure without evidence of attachment. The mass moved with swallowing. In the lateral view, there appeared to be some narrowing of the trachea in the region of the mass. The fifth and sixth right ribs showed old resection, with partial regeneration of the bone in the posterior axillary line. There was evidence of old pleurisy on the right. The lung fields were clear. The heart appeared normal.

Eight days after admission to the hospital, an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. RALPH ADAMS*: May we see the x-ray films?

DR. GEORGE W. HOLMES: The patient had had part of a rib removed. This is the mass that we are interested in. It shows most clearly in this second film, taken with a Bucky diaphragm to

trachea extend high enough to reach the level of the cartilages of the neck?

DR. HOLMES: I think it does.

DR. ADAMS: But does it go up to the level of the thyroid cartilage?

DR. HOLMES: It is questionable whether it does that.

DR. ADAMS: Is the esophagus displaced anteriorly or posteriorly? Or can you tell?

DR. HOLMES: Not from these films, and I do not believe anything is said about it in the notes.

DR. ADAMS: It states in the records, "The displacement of the esophagus appeared to be due to pressure without evidence of attachment." Could you rely on the member of your department who made that statement?

DR. HOLMES: I suspect it was Dr. Richard Schatzki. He has been doing a lot of work on that subject, and I should put considerable weight on what he says. How he finds it out, I do not know.

*Surgeon, Lahey Clinic

DR. ADAMS: The problem in differential diagnosis in this case is to define the type of superior mediastinal tumor that is displacing the esophagus and trachea, causing dyspnea by tracheal compression and producing pain by usurping space at the thoracic inlet, where space is limited. Mediastinal tumors are unsurpassed as stimulators of diagnostic guessing bees, and rarely can the correct guess be supported by critical evidence logically establishing the one diagnosis and definitely excluding all others.

From the history one obtains nonspecific information of both positive and negative value. Radiation of pain to the midclavicular line is observed in many pulmonary and mediastinal lesions, perhaps because anterior cutaneous branches of the intercostal nerves are distributed to that region. The intermittent character of the pain is indicative of an expanding lesion, but expansion can occur in either a cystic or a solid growth. The increasing dyspnea can best be explained by pressure and distortion of the trachea, which was compressed anteroposteriorly and displaced laterally to the left. Other possible explanations, such as heart disease or lung disease, are ruled out by lack of collateral symptoms and physical or x-ray signs of disease in the heart or lungs.

The pale-yellow sputum produced without coughing is puzzling. Most sputum is coughed up. In fact, only sputum lying in the upper trachea and larynx can be raised without coughing. The absence of cough means that there was no irritative lesion of the tracheal or bronchial mucosa, and yet the accumulation of small amounts of pale-yellow sputum, probably mucoid in type, rather than purulent, suggests that there was some mucosal irritation. Extrinsic pressure on the upper trachea could produce this paradoxical situation. Decrease in sputum and dyspnea after x-ray treatment might mean that a malignant tumor, such as lymphoblastoma, had proved sensitive to irradiation, had shrunk in size and had been followed by clinical improvement. It could also mean that the x-ray therapy had merely suppressed secretory function of the tracheal mucosa and that the improvement in dyspnea was coincidental. There is nothing in the clinical summary suggestive of carcinoma of the esophagus or bronchus, that is, no difficulty in swallowing, no food regurgitation, no cough and no hemoptysis: some one of these symptoms would surely be associated with a carcinoma of the bronchus or esophagus casting an x-ray shadow of this size. Also, x-ray films show none of the features to be expected in an invasive lesion of the esophagus or trachea. Cancer will therefore be dropped from further consideration.

It is contrary to usual experience to find a lymphoma of this size localized to one portion of the mediastinum without palpable nodes in the neck, axillas or groins, and with a blood smear so nearly normal. A lymphoma that responded to x-ray treatment with regression in symptoms should have almost disappeared within two months if the treatment was adequate. A tumor of the lymphoblastoma series is therefore believed unlikely.

The history of pneumonia and empyema apparently has no connection with this episode and presumably is included to explain the rib defects and the old pleurisy at the right lung base.

The temperature of 99°F., the white-cell count of 9500 and the polymorphonuclear percentage of 73 indicate slight infection. One possibility is cystitis, because of the report of urine containing albumin and white cells. Another is that the lesion in the chest contained infected material or was surrounded by an inflammatory reaction.

Mediastinal dermoids commonly arise in the anterior portion of the chest, and if they attain sufficient size, most often displace the midline structures posteriorly. This lesion displaced the trachea anteriorly. A dermoid cyst probably is not the answer, although it is ruled out on this point alone. Mediastinal neurofibromas tend to arise in the posterior regions, in proximity to the sympathetic nerves. Consequently they appear in the costovertebral gutter, and before resulting in displacement of the trachea and esophagus, cause erosion of the ribs over which they lie. There is no sign of rib erosion in this case.

Except for the statement that "the displacement of the esophagus appeared to be due to pressure without evidence of attachment," one would consider seriously the diagnosis of a benign tumor of the esophageal wall, such as a fibroma, neurofibroma or esophageal cyst. This statement undoubtedly was recorded by the X-ray Department after careful fluoroscopic study with barium, and must be accepted as final. Approximately a hundred benign tumors of the esophagus have been reported since 1717, and the diagnostic features have been fairly clearly defined. It is improbable that the x-ray staff of this hospital would have missed such a diagnosis.

Any mass of the superior mediastinum that moves with swallowing is probably a substernal goiter, on a purely statistical basis. Substernal goiters, unless they are examples of goiter in aberrant thyroid tissue, always have an attachment to the lower pole of the thyroid gland. In consequence, the tracheal deviation they cause begins

the thyroid cartilage and extends downward to the lower margin of the substernal extension, being maximal at the line of greatest tumor diameter. There is only an exception of 1 per cent to this rule. In the case under discussion, the tracheal deviation did not begin at the thyroid cartilage, but lower at the level of the first thoracic vertebra. Again, substernal goiters descend anteriorly to the trachea, but there is an exception of 1 per cent to this rule. However, 95 per cent of all goiters lying behind the trachea within the chest cause palpable and recognizable irregularity within the neck. Since the neck of this patient was normal, the combined statistical likelihood at she had a substernal goiter becomes 0.05 per cent, leaving it a possibility but not a probability. A so called "bronchiogenic cyst," arising from the right posterior margin of the trachea, could produce the symptoms and findings here recorded, and this is my diagnosis.

DR. EDWARD D. CHURCHILL. I might have been comforted if I had known these accurate statistical chances of the patient's having a substernal goiter, because, not knowing what the mass was, my chief worry was whether it could best be approached through the neck or through the chest. I did not want to operate through the chest and find a substernal goiter. It also crossed my mind that this might have been a parathyroid tumor arising in the posterior mediastinum. High lying anterior mediastinal tumors can in general be

delivered very readily through a cervical incision. I decided on the transthoracic approach and was correct, because this mass was intimately adherent to the lateral aspect of the trachea throughout its whole extent and could not have been exposed from above. It had to be separated from the trachea by sharp dissection, which in some areas exposed the mucous membrane of the trachea.

CLINICAL DIAGNOSIS

Mediastinal tumor (? neurofibroma).

DR. ADAMS'S DIAGNOSIS

Bronchiogenic cyst.

ANATOMICAL DIAGNOSIS

Bronchiogenic cyst, arising from trachea.

PATHOLOGICAL DISCUSSION

DR. MALLORY. I have the specimen here. It was cystic, filled with very thick, partially inspissated, mucoid material. In its walls, numerous plaques of cartilage could be easily felt. On microscopic examination, it is evident that it is lined with ciliated epithelium and that it contains numerous mucous glands, cartilaginous plaques and occasional bundles of smooth muscle, in other words, all the various structures that go to make up the trachea or bronchi. Therefore, it can be classed as a bronchiogenic or tracheal cyst, as Dr. Adams predicted.

CESAREAN SECTION IN MASSACHUSETTS

THE five-year study of cesarean sections in Massachusetts, sponsored by the Massachusetts Department of Public Health and the Section of Obstetrics and Gynecology of the Massachusetts Medical Society and supervised by Dr. Robert L. DeNormandie, has been completed, and a summary of the results appears in this issue of the *Journal*. The compilation and analysis of even a limited amount of data on such a large series of cases is an arduous task, and Dr. DeNormandie and his associates deserve a large measure of credit for carrying it through to completion.

The report necessarily falls far short of being a thorough statistical study, but it furnishes considerable prima-facie evidence of abuse of this operation throughout the State. How extensive this abuse is, in view of the limited information available, must be a matter of speculation. The two most frequent indications given for primary section were contracted pelvis or disproportion and dystocia. There is no way of knowing precisely what was meant by "dystocia." The term simply means difficult childbirth. Presumably what was meant in most cases was so-called "cervical dystocia" or labor which, though prolonged, was ineffectual in dilating the cervix. These two indications combined account for 3234 cesarean sections, practically 1 per cent of the total births. It hardly seems plausible that in 1 out of every 100 cases of childbirth in Massachusetts, a section is necessary because the pelvis is too small, the baby too big or the labor ineffective. The third most frequent indication for primary section was placenta previa, of which there were 1021 cases. If all these patients had placenta previa, the incidence of that complication was about 1 in 327 births, and if there were any patients with placenta previa who were not delivered by cesarean section, the incidence was, of course, correspondingly greater. Such a frequency of placenta previa is scarcely credible. If the repeat sections are excluded, it appears that in 330,464 births there were 7763 primary sections—an incidence of about 1 in 43. The mere perusal of the indications given for some of these sections is sufficient to arouse suspicion. In 150 cases, they are, to judge by the samples given, utterly ridiculous, and in at least 170 others, they are manifestly indefensible.

The mortality in this series of cesarean sections is extraordinarily low—2.5 per cent. A low mortality, however, is not an unmixed blessing, because it is a contributory cause of the reckless use of the operation. With a mortality risk of this order of magnitude, it is not at all improbable that even a busy physician will practice many years without having a death follow cesa-

ean section, and undoubtedly many a physician much more influenced by his personal experience than by a statistical fact. When the mortality of cesarean section is between 1 and 2 per cent, the operation is not more hazardous than are some of the more difficult and complicated pelvic deliveries, and if the operator in a difficult or complicated pelvic delivery is not especially trained in obstetrics, section is probably less hazardous. When, however, a healthy woman who could be delivered simply and easily through the pelvis is subjected to cesarean section, her chance of dying is multiplied about ten times. This is a truth that certainly is not widely known among the laity and seems not to be comprehended by many physicians.

The extensive use of cesarean section is not, of course, so great a factor in total maternal mortality as it is often said to be. A large proportion of all maternal deaths follow cesa-

rean section, but this is due, in part at least, to the fact that the operation is often employed to deliver patients with such serious complications as heart disease, nephritis, severe pre-eclampsia and placenta previa. These patients run a much greater risk than normal patients, regardless of how they are delivered. During the five years covered by this study, the total maternal mortality dropped from 4.1 to 2.9 per 1000 live births. The incidence of cesarean section, however, remained practically constant, and the slight drop in cesarean mortality is quite insufficient to account for the drop in total mortality. What is needed is not simply fewer cesarean sections, but better obstetrics, and the really disturbing feature of this report is not the number of sections done, nor the frequency of foolish indications, but the indirect evidence that there is still a great deal of bad obstetrics being done in Massachusetts.

OCCUPATIONAL SKIN DISEASE

WARTIME industrial activities have provided the Nation not only with a host of victims killed and permanently disabled by injury but also with much disability because of cutaneous damage. Not everyone is aware of the fact that 65 per cent of disease due to occupational factors concerns the skin, or that the consideration of occupational liability may arise in a fifth of all cases with cutaneous involvement, especially if the hands and arms alone are affected. Furthermore, the amount of disability produced by the effects of industrial processes on the skin has increased in the last few

months, owing, in all probability, to employees in new and unfamiliar occupations, perhaps inadequately trained in the cutaneous hazards involved and the proper care of the skin, to the speeding up of industrial processes, to the introduction of new ingredients and, perhaps, to other factors.

Particularly disturbing are the reports of increased irritation of the skin by cutting oils used in the manufacture of planes, tanks and guns. Numerous other examples of cutaneous hazards in war industries are cited by Downing elsewhere in this issue of the *Journal*.

For the medical profession, the early detection, the proper treatment and the prevention of occupational dermatoses constitute a real challenge. A review¹ of the recent report of the Committee on Industrial Dermatoses of the Section on Dermatology and Syphilology of the American Medical Association defines the criteria for the recognition of these diseases, and these points are further discussed in a recent issue of the *Journal*.² Proper treatment requires recognition of the causal factor and the development of proper protective measures or the elimination of that factor; and it implies the avoidance of presumably therapeutic

MASSACHUSETTS MEDICAL SERVICE

doctors had become participating
physicians in the Blue Shield.

substances that may exaggerate an already inflamed skin—20 to 25 per cent of all cases of dermatitis are due to some form of therapy. In prevention, however, lies the real answer. The working out of prophylactic measures against a particular cutaneous hazard is often difficult, but much progress has been made, as is indicated in Schwartz and Tulipan's³ recent textbook on the subject and in recent bulletins issued by the United States Public Health Service.

Occupational dermatoses are for the most part preventable. In these days, it is the duty of every physician to contribute to the war effort by recognizing these cases, by returning such patients to work at the earliest possible moment and by preventing further disability to them and other employees.

MEDICAL EPONYM

ROMBERG'S SIGN

Moritz Heinrich Romberg (1795-1873), professor and director of the Royal Polyclinic Institute of the Friedrich-Wilhelm University, Berlin, described this sign in his *Lehrbuch der Nerven-Krankheiten des Menschen (Textbook of Human Nervous Diseases)*, (Berlin, 1851: Vol. 2, p. 185). A portion of the translation follows:

If the patient is asked to close his eyes while standing upright, he immediately begins to sway and reel. . . . I called attention to this pathognomonic sign ten years ago (according to my observation, it does not occur either in other paralyses or in uncomplicated blindness) and have since never failed to find it in any of my numerous patients with this disease.

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE ON MATERNAL WELFARE A PLEA FOR BREAST FEEDING

The war emergency has precipitated many changes in activities for the public good. Perhaps no more important contribution, particularly in view of the threatened shortage of physicians, can be made for this and the coming generation than by renewing the efforts to urge mothers to nurse their babies.

In their textbook, *Diseases of Infancy and Childhood*, Holt and McIntosh state:

Maternal nursing is the natural and ideal method of infant feeding. Every mother should nurse her infant unless there are weighty reasons to the contrary. The large majority can do so. The physician should do all in his power to encourage maternal nursing and to insure its success.

This statement of facts cannot be more succinctly expressed. The depleted ranks of the medical profession, the increase in the birth rate and the modified and often unfavorable conditions for infant care emphasize the importance of the above statement and the duty of the physician in this emergency.

Lactation can be promoted by the practice of the accepted principles of prenatal care, with emphasis on a well-balanced diet. And, of great importance in establishing lactation are skillful obstetric care and the proper education of nurses in the technic of breast feeding. Psychology plays no little role, especially in the early stages of lactation, and the nurse, by her skill and encouragement, is often the determining factor.

The technic of nursing consists in regularity of feedings, preferably every four hours on both breasts, five or six times daily. Complete emptying of the breast stimulates the secretion of milk, and a normal infant secures its quota of milk in twelve minutes of active nursing. Although the duration of each nursing cannot be empirically stated, it certainly is undesirable to urge babies to nurse beyond a twenty-minute period.

A common error is to omit nursing because the baby has not gained according to certain standards. A stationary weight or a slow gain for a week is often followed by an adequate supply of mother's milk. Furthermore, vomiting and loose stools are too often attributed to "poor milk." In general, a mother's milk is suitable for her infant, and these symptoms are only rarely of importance.

Since over 80 per cent of all babies in Massachusetts are born in hospitals, it is the responsibility of the nursing staffs and the visiting physicians to institute all the procedures that are necessary to ensure maternal nursing.

DEATH

MIKOLAITIS — CASIMIR JOHN MIKOLAITIS, M.D., of Lawrence, died July 7. He was in his fifty-ninth year. Dr. Mikolaitis received his degree from the Chicago College of Medicine and Surgery in 1914. He was a former member of the Massachusetts Medical Society.

WAR ACTIVITIES

OFFICE OF CIVILIAN DEFENSE

SUPPLEMENTAL STAFFS FOR EMERGENCY BASE HOSPITALS

Selected hospitals and medical schools in the coastal states have been invited by the Surgeon General of the United States Public Health Service to organize affiliated staff units that will be ready to serve when needed to supplement the medical staffs of emergency base hospitals, now being designated by the Medical Division of the Office of Civilian Defense. These units resemble the affiliated hospital units of the Army except that they are smaller. They are being organized to assure suitable status and remuneration for physicians who may be called on in the event of an enemy attack in their locality to care for casualties and other patients who have been evacuated to the interior of their region.

The designation of emergency base hospitals and the formation of affiliated units are part of a joint hospital program of the Medical Division of the Office of Civilian Defense and the United States Public Health Service. The program is authorized under an agreement concluded March 2, 1942, between the Federal Security Administrator and the director of the Office of Civilian Defense.

Physicians in the affiliated units will be commissioned in the inactive Reserve Corps of the Public Health Service. Unless an urgent need for their services should arise, they will remain on an inactive status for the duration of the war. They will be called to active service only if hospitals in their regions must be evacuated and the civilian population must be moved because of military necessity. Activation of the units will take place by order of the Surgeon General at the request of the chief medical officer of the Office of Civilian Defense on advice of

The regional medical officer and the state chief of Emergency Medical Service in charge of the affected areas.

The commission will be in grades ranging from passed assistant surgeon to senior surgeon, and when units are activated, these officers will have the rank, pay and allowances equivalent to those of officers in the armed forces.

Institutions invited to form units are asked to nominate an outstanding physician or surgeon as unit director, who, if he meets the physical and other requirements, will be commissioned senior surgeon in the Public Health Service Reserve. The unit director will then nominate the remainder of the staff, and appointments will be made after clearance through the state chief of Emergency Medical Service. Nominations are to be limited to male physicians over forty five years of age, to those under that age who have physical disabilities that disqualify them for military service but that do not interfere with their professional activities, and to women physicians.

To avoid serious depletion of the professional staffs in the medical schools and hospitals of the target areas, the Surgeon General has recommended that medical schools draw their affiliated units in part from associated hospitals and that nonteaching hospitals invite physicians from other qualified hospital staffs to collaborate.

MISCELLANY

RÉSUMÉ OF COMMUNICABLE DISEASES IN MASSACHUSETTS FOR AUGUST 1942

DISEASES	AUGUST 1942	AUGUST 1941	FIVE YEAR AVERAGE*
Anterior poliomyelitis	2	45	44
Chicken pox	121	125	107
Diphtheria	12	6	11
Dog bite	1077	998	1099
Dysentery, bacillary	4	79	20
German measles	83	31	25
Gonorrhea	49	283	401
Measles	296	281	287
Meningitis meningococcal	19	3	5
Meningitis other forms	27	4	—†
Mumps	21	23	150
Paratyphoid infections	13	9	19
Pneumonia lobar	121	4	100
Scarlet fever	224	195	118
Syphilis	354	341	391
Tuberculosis pulmonary	303	270	297
Tuberculosis other forms	74	24	30
Typhoid fever	10	8	10
Undulant fever	4	13	4
Whooping cough	673	575	520

*Based on figures for preceding five years.

†After bacillus meningitis only other form reportable previous to 1941.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from Braintree, 1; Weymouth, 1, total, 2.

Diphtheria was reported from Athol, 1; Cambridge, 1; Fall River, 3; Lowell, 1; New Bedford, 1; Somerset, 1; Somerville, 1; Springfield, 1; Woburn, 2, total, 12.

Dysentery, bacillary, was reported from Boston, 1; Danvers, 1; Lowell, 1; Salem, 1, total, 4.

Encephalitis, infectious, was reported from Weston, 1; Weymouth, 1, total, 2.

Lymphocytic choriomeningitis was reported from Worcester, 1, total, 1.

Malaria was reported from Boston, 1; Camp Edwards, 3; Fort Banks, 1; Quincy, 1, total, 6.

Meningitis, meningococcal, was reported from Boston, 6; Brockton, 1; Cambridge, 2; Dedham, 1; Fort Devens, 1; Fitchburg, 2; Plymouth, 1; Revere, 2; South Hadley, 1; Springfield, 1; Worcester, 1, total, 19.

Meningitis, other forms, was reported from Natick, 1; Revere, 1, total, 2.

Paratyphoid infections were reported from Amherst, 4; Arlington, 1; Leominster, 1; Lowell, 1; Methuen, 1; Southwick, 1; Tyngham, 1; Woburn, 2; Worcester, 1, total, 13.

Septic sore throat was reported from Boston, 1; Lynn, 1; Milton, 1; Waltham, 1; Worcester, 1, total, 5.

Tetanus was reported from Holyoke, 1, total, 1.

Trachoma was reported from West Boylston, 1; Worcester, 1, total, 2.

Typhoid fever was reported from Arlington, 1; Beverly, 1; Cambridge, 2; Lynn, 1; Quincy, 1; Rockland, 1; Worcester, 3, total, 10.

Undulant fever was reported from Cambridge, 1; Clarksburg, 1; Fitchburg, 1; Townsend, 1, total, 4.

Communicable diseases reported at figures above their five year averages were chicken pox, diphtheria, German measles, gonorrhea, measles, pneumonia, scarlet fever, pulmonary tuberculosis, whooping cough and mumps. The last disease had been previously reported at record high figures for eleven of the preceding twelve months.

Meningococcal meningitis was reported at a record high figure.

Anterior poliomyelitis reached a record low figure during this month.

Diseases reported at lower figures than their five year averages include dog bite, bacillary dysentery, paratyphoid infections, syphilis and tuberculosis, other forms.

Typhoid and undulant fevers were both reported at figures equal to their five-year averages.

Two cases of animal rabies were reported, one from each of the foci in the southeastern and northeastern sections of the State.

CORRESPONDENCE

APPROVED LABORATORIES FOR PREMARITAL BLOOD TESTS

To the Editor: The list of laboratories approved for performing premarital blood tests has recently been revised. There are eight such laboratories on the present list in addition to the Wassermann Laboratory of the department. These are:

Boston

Boston Dispensary
Boston Health Department
Leary Laboratory
Massachusetts General Hospital
Peter Bent Brigham Hospital

Brockton

Health Department

New Bedford

St. Luke's Hospital

Springfield

Mercy Hospital

Several other laboratories have made application for approval. It is likely that others will be added to the list about January 1.

PAUL J. JAKUBOWICZ, M.D.
Commissioner of Public Health

State House
Boston

Cholesterol is synthesized in the human body. The excess is probably ingested in the form of egg yolk, milk and animal fats. Needs for this substance are greatest in times of rapid cell formation. Egg yolk is intended for the embryo, and milk for the nursling. Metabolism of cholesterol is most efficient in the young, but heredity is certainly a factor. The tissue content of cholesterol increases with age, whereas the need for it grows less. Women mobilize this substance during pregnancy, possibly for the use of the embryo, and show minor mobilization during menstruation. They are less susceptible to atherosclerosis than men.

Excess cholesterol, then, is the cause of atherosclerosis, but stresses determine the localization of the lesions. Sex and thyroid secretions influence cholesterol metabolism, and age and heredity are modifying factors. Diets with limited or absent cholesterol should prevent atherosclerosis, and this may be accomplished by the substitution of vegetable oils, whose sterols are not absorbed, for animal fats.

The lesions of coronary sclerosis are almost exclusively atherosclerotic. The frequency of coronary disease is related to the unusual stresses to which the vessels are subjected. These vessels arise directly from the aorta in a region where there is maximal stress when the aortic cusps close. Moreover, circulation is cut off from the muscular branches by compression as the ventricles contract. At the same time, the main vessels and their sub-epicardial branches are not compressed, but are filled with blood under systolic pressure, without being able to empty themselves. The main coronary circulation is during diastole. Because of these stresses, normal coronary arteries develop characteristic thickening of the intima to produce a "buffer layer."

Advanced coronary sclerosis in patients as young as twelve years indicates that atherosclerosis is not entirely a disease of old age. But the type of lesion varies with age. In youth, excess cholesterol provokes a growth of loosely textured fibroblastic tissue. As the lesions enlarge, diffusion of nutritive material from the circulating blood becomes inadequate, and necrosis of the deep layers results. When the lesions become even larger, vascularization by capillaries from the lumen, or less commonly from the vasa vasorum, supplies the nutriment. All advanced coronary lesions are vascularized. The lumen is narrowed by eccentric or concentric thickening of the intima. Spasm may result in rupture of capillaries, fibrin formation and fibrinoid necrosis. With extension of the necrosis to the endothelium, thrombosis follows, and is the usual cause of sudden death.

In middle age, more collagen is formed, and scarring is typical of this period. Narrowing of the lumen, with coronary insufficiency and chronic vascular myocarditis, is frequently found at post-mortem examination. Spasm may result in sudden death or in infarction without anatomic occlusion of the vessels, particularly in hypertensive heart disease. Thrombosis is less common than in youth, whereas calcification becomes commoner.

In old age, atherocheumas occur frequently because of lowered tissue reaction to excess cholesterol. Occlusion may be caused by rupture of such a lesion. Scarring persists from earlier periods, and calcification is practically the rule.

Rupture through the necrotic tissues of a cardiac infarct may cause death by hemopericardium and cardiac tamponade. Rupture of an atherosclerotic coronary artery may likewise lead to hemopericardium. Dissecting aneurysms of the coronary arteries are rare. Infarcts are re-

paired by granulation, sometimes with pericardial adhesions. Mural cardiac thrombi may lead to systemic embolism. The scar tissue repairing an infarct may undergo stretching, producing a cardiac aneurysm. Coronary thrombi undergo organization if the patient lives, sometimes with canalization. But, usually, the blood flow is re-established around the region of thrombosis by a collateral circulation. Anastomoses between coronary arteries increase with age. In conclusion, it was pointed out that coronary occlusion may be symptomless, or may cause mild or serious illness; it may result in sudden death with ventricular fibrillation or death so instant as to suggest immediate cerebral arrest with cardiac and respiratory standstill.

The discussion was opened by Dr. Alan Moritz, who questioned the existence of coronary spasm. But Dr. Leary replied that coronary infarcts without thrombosis can be demonstrated at autopsy and that death sometimes follows characteristic manifestations of coronary occlusion when minor post-mortem lesions are present, if any. Dr. Samuel Levine pointed out that in a study of 100 young patients with angina pectoris, 96 were males. He added that this indicates a strong endocrine factor; however, the localization of the atheromatous lesion seems to be a familial factor, possibly dependent on some congenital anatomic peculiarity. Dr. Leary suggested that the prevalence of the proximal portion of the left coronary artery as a site for a single thrombosis may be explained on the basis of the sharp angulation of this vessel and its main branch, which create a mechanical hazard in a person who is unable to handle cholesterol adequately.

In answer to questions from the floor, Dr. Leary stated that the blood cholesterol levels in experimental rabbits, as well as in patients with hypothyroidism, are elevated. At autopsy, the amount of atherosclerosis is roughly proportional to the amount of hypothyroidism, whereas hyperthyroid patients definitely have less or no atherosclerosis. The changes described in the liver and adrenal glands in the rabbit have not been observed in man. The relatively enormous accumulations of excess cholesterol in these organs in the experimental rabbit, whose normal diet includes no cholesterol, account for this difference. Lesions due to intermittent accretions of excess cholesterol over a period of years in man may be reproduced in weeks or months in the rabbit.

BOOK REVIEW

Neuroanatomy. By Fred A. Mettler, M.D., Ph.D. 4th ed., cloth, 476 pp., with 337 illustrations, including 30 in color. St. Louis: The C. V. Mosby Company, 1942. \$7.50.

This is a new and valuable addition to the textbooks of neuroanatomy. The first part deals with the gross aspects of the neural systems, and the second, with microscopic anatomy. The text is clear, concise and simple in terminology. The illustrations, some in color, are a particular feature of the book. The drawings are excellent and the labeling adequate, and the figures are well correlated with the text. Adequate references to the literature are given, and the index is generous.

The author is to be congratulated on the quality of his product. In a field already covered by many other books, he has succeeded in writing a text that is superior to most. The format and press work are well fitted to the text. The book is worthy of the highest endorsement.

SYMPOSIUM: MINOR PSYCHIATRIC DISTURBANCES IN WAR AND CIVILIAN LIFE

THE DIAGNOSIS OF THE PSYCHONEUROSES

DONALD J. MACPHERSON, M.D.†

BOSTON

IN a discussion of the phenomena included in the term "psychoneuroses," it is essential to realize that the word does not apply to a specific disease but rather to the quality and degree of adjustment that a person makes to the problem of living. It relates to his satisfaction with life, the efficiency with which his abilities are mobilized and his effect on other people.

Although in certain cases there may be a constitutional predisposition to behave in a neurotic manner, it appears equally true that under fatigue, sufficient stress or a particular kind of stress, a normal person may for a time behave in a neurotic manner.

Before the actual experience with bombing in Britain, there was apprehension that civilians exposed to the intense and terrifying conditions created by air raids would react with panic, hysteria or neurosis. As a matter of fact, this has not happened. Under this kind of stress, pride or the fear of what other people might think is sufficient to maintain a freedom from neurotic manifestations. People become habituated to the threat of destruction very quickly and go about their affairs. There may be anger at the enemy, but that might well be classified as righteous indignation. Pathologic mental disturbance is extremely rare. Among people known to be neurotic, about 25 per cent have actually improved under war strain. This may be because the demands and opportunities for activity under the altered conditions are more vital than the issues creating the neuroses. Twenty-five per cent are made worse, and 50 per cent show little or no change. Children appear to be even

less disturbed by air raids than adults. In general, there is a tendency for them to imitate adult behavior. It is interesting that the disorganization of a regular routine of life is more frequently a cause of neurotic behavior than the air raids per se.

In normal civilian life, some patients who seek help and are recognized as neurotic may be in trouble either because of a temporary conflict brought on by unusual environmental or personal difficulty that will pass or change with time, or because of a type of personality that has difficulty in adjusting to a normal environment most of the time. In the latter group, certain tendencies, which constitute a variation from what might be considered mature adult behavior, appear very often. A healthy-minded adult has acquired a capacity to observe his environment and appraise himself with some objectivity. With these data, action is initiated with respect for real limitations and without excessive optimism or pessimism about the results. He does the best he can and is willing to make mistakes and learn from them.

The neurotic has a strong subjective bias. He has intense wishes and fears. His behavior tends to be governed by attempts to protect his own feelings. He is prone to disregard facts that are inconsistent with his wishes, and to have difficulty in learning from experience. He may be puzzled, angry or hurt at the ineffectiveness of his efforts, but he continues to make the same mistakes. There is a strong tendency to assume that the trouble is with other people, or bad luck. One is reminded of the poor workman who blames his failure on the tools.

The neurotic does not consider himself realistically, as an object in a world of objects subject to natural law. He feels special, and eternally hopes

PSYCHIATRIC COMPONENTS IN MEDICAL DISEASE: PSYCHOSOMATIC MEDICINE*

JACOB E. FINESINGER, M.D.†

BOSTON

DURING the last two decades, a new field has opened for the investigation of certain medical illnesses in which psychiatrists have shown interest. This field, often referred to as psychosomatic medicine, deals primarily with medical and surgical diseases that are properly within the province of internists, surgeons and medical specialists. The illnesses studied are those in which there exists a pathologic lesion, in contrast to the psychoneuroses, — especially hypochondriasis, — in which no known pathology exists. The etiology of these illnesses is as a rule unknown. Repeated observations have demonstrated that stresses and strains arising from the environmental situation and from difficulties in the personality of the patient play a significant role in the precipitation and in exacerbations of these illnesses. From studies in the neuroses and psychoses, psychiatrists have become familiar with the significance to the patient of specific situations and with the intricacies of personality function. This information has been applied to psychosomatic medicine in the hope of throwing light on the puzzles presented to the physician by these illnesses. The systematic approach to these special problems is still in its preliminary stage, and not more than the surface has been scratched. Yet sufficient work has already been done to indicate the validity of this approach. This paper reviews briefly the most striking studies that have appeared in this field.

It has been found that certain organ systems seem to be more readily involved than others. These systems are essentially those whose activities are actuated by the autonomic nervous system. One is apparently dealing with episodic reactions, which in many cases result in irreversible pathologic processes. The typical feature of these illnesses is that they are of long duration and characterized by exacerbations and remissions; they strongly resist treatment. Certain factors, especially allergic factors, play a role in the development of some of these disorders and yet do not alone explain the exacerbations and remissions. Of the many and confusing interrelations presented by the study of these illnesses, the best established seems to be a temporal relation between exacerba-

tions and events or situations confronting the patient. In a few illnesses, a relation between the clinical diagnosis and the personality of the patient seems established from several sources. The role that situations and personality factors play in the etiology of the illness is least well established.

Studies that have been undertaken have made use of three methods of approach. Most of the studies concerned with establishing correlations depend on the history obtained from the patient or from some other source, by means of interviews or questionnaires. Even though large numbers of patients can be studied in this way, the limitations and sources of error are obvious. One would have to have access to data dealing with every single exacerbation and remission of the illness, a task hardly possible by the history method. The dependence on the memory of the patient and the avoidance of suggestion on the part of the interviewer represent the major difficulties. In dealing with the personality traits of patients, one is faced by the added difficulty of using descriptive words, about which there is little agreement among investigators.

Another approach concerns itself with the careful and intensive study of small groups of patients, either by intensive psychiatric study or by rigid psychoanalytic procedure. Here, too, correlations are drawn between situations and the exacerbation or remission of symptoms. In addition, attempts have been made to modify the patients by means of various psychotherapeutic approaches so that the same persons would no longer react pathologically to the presenting stimuli. There are also therapeutic reports and a few follow-up studies in some illnesses.

A third and most significant approach has been used in a very few studies. This is the experimental approach, which in these problems attempts first of all to find out what specific situations or ideas correlate with the symptoms. Attempts are then made to bring about exacerbations by carefully introducing discussions about these situations or ideas into the interview during a state of remission, avoiding as much as possible the introduction of other complicating variables.

The illnesses in which information is moderately complete are presented in some detail. The others are briefly mentioned. No attempt is made to

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 27, 1942.

†Assistant professor of psychiatry, Harvard Medical School; psychiatrist, Massachusetts General Hospital.

include all the known facts. The literature has been comprehensively reviewed by Dunbar.¹

CLINICAL STUDIES

Gastrointestinal Diseases

That patients react with their gastrointestinal symptoms to various types of situational and emotional stimuli has long been known.² Cannon³ has clearly pointed out that states of worry and anxiety, grief, anger and other violent emotions can start a vicious circle leading through impaired digestion to mild inflammation and to impaired absorption, resulting in the vicious circle of emotional disturbances. Studies on patients with gastric ulcer, duodenal ulcer, esophageal spasm⁴ and gastropasm⁵ have appeared in which the role of emotional factors has been considered. Recently, Mittelman, Wolff and Scharf,⁶ in a study of patients with gastritis, duodenitis and peptic ulcer, note that epigastric distress, nausea and even bleeding are precipitated or increased by emotional states. Anxiety, whether recognized by the patient or not, is an outstanding component of these emotional disturbances. In experimental work on patients with peptic ulcer, these authors report that such feelings as embarrassment, resentment, anger, anxiety and anxious anticipation are associated with a rise in gastric acidity and in total volume of secretion, with high or continuous peristaltic activity and hyperemia of the gastric mucosa. Feelings of security and relaxation are associated with low acidity and with less peristaltic activity. They postulate that the increased acidity, motility, hyperemia and even hemorrhage may have a bearing on the genesis of gastric and duodenal lesions found in the clinical picture of gastritis and duodenitis. The fact that mucosal erosions result from prolonged stimulation of the vagus⁷ and also follow the intravenous⁸ and intraventricular injection of acetyl-choline indicates that the parasympathetic outflow is most probably involved in the production of these lesions. It is not yet clear what factors determine the irreversible pathology that occurs in some cases.⁹

Psychosomatic studies on mucous colitis (mucous diarrhea), constipation, spasm of the colon and ulcerative colitis have been reported. Most of the work deals with mucous colitis, which was first well described by DaCosta.¹⁰ Later authors emphasized the secretory and motor changes,¹¹ the inflammatory basis of the illness¹² and the role of food allergy.¹³ White, Cobb and Jones,¹⁴ in a broad study of mucous colitis, support the thesis that this disease is a physiologic disorder of the colon brought about by the action of the parasympathetic nervous system. The pathologic changes

seen can be brought about experimentally by the use of cholinergic drugs,¹⁵ although these changes have not been produced by the stimulation of the sacral outflow of the parasympathetic nervous system. In 92 per cent of the 56 psychogenic cases studied by White, Cobb and Jones, emotional tension was present, and the authors believe that this emotional tension was the commonest cause of the parasympathetic stimulation. In the more neurotic group of their patients, exacerbations of symptoms were associated with emotional tension in 56 per cent, whereas in the less neurotic group, a relation between tension and exacerbations of symptoms was found in 85 per cent. The higher correlation obtained for the less neurotic group was believed due to the fact that the emotional disturbances in this group were more frequently recognized, since "the sources of tension were always superficial and more readily understandable."

From a psychoanalytic study of a small number of patients, Alexander¹⁶ reported three personality types associated with gastrointestinal symptoms. He considered that patients with primarily gastric symptoms had personality features characterized by activity, independence and efficiency. Of the patients with intestinal complaints, he distinguished a "colon type" with diarrhea as dependent persons who had marked tendencies toward giving, with feelings of obligation and guilt. He also differentiated a "constipation type," characterized by stinginess, dependence and need for accepting with no guilt and no need for giving. White, Cobb and Jones¹⁴ confirmed the existence of these types among their patients. They were unable to corroborate fully the correlation postulated by Alexander between the colon and constipation types and the presence of constipation or diarrhea. White, Cobb and Jones found that the emotion most characteristic of their patients was that of resentment. Patients with mucous colitis were also conscientious, rigid, meticulous people with compulsive tendencies. As a result of this rigidity of thinking and the tendency to dwell on disturbing topics, the tension was sustained over long periods. This protracted state of affairs is believed to result in the formation of symptoms.

In patients with ulcerative colitis, correlations between the exacerbations and special situations have been reported by Murray,¹⁷ Sullivan¹⁸ and Wittkower.¹⁹ Lindemann²⁰ has most recently pointed out that these patients present a psychiatric disturbance characterized by apathy, a marked difficulty in communicating matters of emotional concern and a defect in "differentiating reality from subjective falsifications." Daniels²¹ has em-

phasized in this group the need for dependence on some member of the family, usually the mother. Conflict develops in situations, such as engagement and marriage, that threaten this dependence. This conflict can be the precipitating factor.

Allergic Diseases

Investigations have been made on various diseases associated with specific allergens. Of these, the most work has been done on asthma²² and on certain types of cutaneous disturbances, notably atopic dermatitis.²³ That the respiratory function can be influenced by emotions and situations has long been known. More recently, this question has been re-investigated, and it has been shown that, in anxiety states and hysteria, changes in rate of respiration, in total ventilation and in the pattern of respiration are associated with certain ideational and sensory stimuli.²⁴ Irregularities in respiratory rhythm are described in anxiety states,²⁵ and marked episodes of hyperventilation have been seen in hysteria.²⁶ These changes are all episodic and reversible.

Bronchial asthma. Many sporadic studies show that in acute attacks of asthma not only exacerbations of the condition but also, at times, remissions are associated with situations that provoke acute anger²⁷ or other violent affects. The demonstration of sensitivity on the part of patients to many allergens not only has removed the emphasis from the emotional factors for a time but also has made it difficult to exclude the possibility that every asthmatic attack is caused by an allergen unsuspected in the situation. Yet, in many cases, the presence of allergens to which the patient is sensitive does not alone explain the attack. Such factors as fatigue and emotional disturbances have been secondarily involved. More recently, evidence has been accumulating that asthmatic attacks can be brought on by hypnosis in asthmatic patients,²⁸ and even by direct suggestion²⁹; the fact that several authors have used psychotherapy with good results when somatic therapy failed³⁰ has reopened the problem for systematic investigation.

McDermott and Cobb³¹ found that in a two-hour interview an emotional component could be found in 37 out of 50 consecutive cases of asthma admitted to the Massachusetts General Hospital. The same finding was mentioned by Halliday³² in a series of 30 patients. French and Alexander³³ have recently reported a study of 27 patients with bronchial asthma who were psychoanalyzed at the Chicago Institute of Psychoanalysis. Nineteen of these patients were under treatment for long periods, and the results have been reported in detail. The thesis advanced by this group of investigators is that asthmatic patients tend to respond

to increased respiratory stimulation with asthmatic attacks. Hence, attacks follow situations or experiences that induce respiratory stimulation, such as intense emotion, muscular exertion and hurry. They also note the paradoxical observation that, in some cases, intense emotion has been known to bring about the cessation of an attack. As a tentative explanation of the paradox, French and Alexander suggest that the precipitating situations are those in which the patient "must suppress his emotion or in which he finds himself completely helpless to give adequate expression to it." They refer to the observation of other authors³¹ that in cases in which the attack ceases on sudden emotion, adrenalin is mobilized in the blood stream; this mechanism apparently does not operate during the emotional conflict induced by the precipitating situation. From their analytic material, they find that the conflict situation relates to earlier situations that threaten to separate the patient from a female figure—a mother figure. The patient responds to this state of helplessness by an asthmatic attack, which according to these authors has the symbolic significance of a suppressed cry.

Deutsch³⁴ has postulated that the asthmatic patient undergoes a development characterized by an "affection" of the respiratory apparatus in early childhood associated with certain emotional factors at that time, emotional upsets in childhood, acting as conditioning factors, and the development of a marked dependence on a hated, domineering and aggressive mother.

Rogerson, Hardcastle and Duguid³⁵ report that practically all their asthmatic children were characterized by marked anxiety and lack of self-confidence. In the adult group, French and Alexander³³ found that their patients all suffered from a deep-seated insecurity and a more or less intense need for parental love and protection.

Atopic dermatitis. Atopic dermatitis is another chronic illness in which there are marked exacerbations and remissions. Most of the patients with this disturbance show sensitivity to specific allergens, and many have personal or familial histories of other allergic disturbances. Becker³⁶ has repeatedly pointed out that fatigue may play a major role in the etiology through its effect on the underlying "protoplasmic irritability," which, according to him, is constitutional. Stokes³⁷ has emphasized the relation between skin disturbances and psychosexual difficulties. Other workers have pointed out the significance of blushing,³⁸ exhibitionism³⁹ and the need for self-punishment.⁴⁰

Greenhill and Finesinger⁴¹ have found that situations dealing with work problems, family difficulties, psychosexual problems and changes in the

physical environment were associated with the exacerbation of symptoms. In this respect, the results confirm earlier studies of Becker and Obermayer.⁴³ These events were associated primarily with feelings of hostility, insecurity and depression. On the other hand, a smaller series of patients with lupus erythematosus discoides also showed a relation between situations and exacerbation of symptoms. This correlation was not nearly so striking as that in the atopic patients. The patients with atopic dermatitis had the characteristics of the compulsive obsessive type, as well as difficulty in their relations with other people. There was a great incidence of feelings of hostility rarely shown in overt action. These patients were sensitive and tended to suppress feelings of anger. They entertained feelings of inadequacy, lacked self-confidence and were depressed and notably shy.

Other diseases Certain studies have been concerned with urticaria,⁴² angioneurotic edema,⁴³ hay fever⁴² and the common cold.⁴⁴ Saul and Bernstein⁴² believe that states of repressed, intense, frustrated longing are of primary importance complementing allergic factors. They also mention the interesting fact that urticaria appeared in 1 case when weeping was repressed and often terminated when the patient wept. Saul⁴² has more recently confirmed the role of repressed longing in cases of hay fever and common cold.

Cardiovascular Diseases

Some of the earliest observations deal with the effects of situations and emotions on the cardiovascular system.⁴⁵ Acute cardiac and cerebral insults have been repeatedly described following emotional outbursts. In some cases, excitement and anger apparently bring about a rise in blood pressure, which causes breaks in peripheral vessels already weakened by an existing lesion. Likewise, acute transitory changes in blood pressure,⁴⁶ pulse rate⁴⁷ and cardiac output⁴⁸ are known to be associated with disturbing situations and with various emotions. Similar episodes are known to produce exacerbations in other illnesses, such as Raynaud's disease⁴⁹ and essential hypertension,⁵⁰ in which a vascular lesion already exists. Distinct personality trends have been described by Hamilton⁵¹ in patients with elevated blood pressures.

The more detailed studies are concerned with essential hypertension. It has been suggested that essential hypertension is associated with unstable and tense personalities. The behavior of such persons is characterized by increased psychomotor activity.⁵²⁻⁵³ Alexander⁵⁴ and Saul⁵⁵ have studied several patients psychoanalytically in whom a diagnosis of essential hypertension was made. They state that the basic problems in these patients are

concerned with attempts at handling their dependence. This dependence has its origin in an early relationship to a dominating parent, and leads to the formation of a pattern of general behavior to which the patient adheres thereafter. It is this submission to authority that the patient struggles against with rebellion and hostility. The conflict centers about the expression or repression of this hostility. During periods when either the dependence or the hostility could be gratified, the blood pressure was markedly lower. This formulation has been confirmed by Miller⁵⁶ in a study of psychotic patients with high blood pressure.

Endocrine Disturbances

Numerous studies in the literature deal with the relation between various endocrine disturbances and the psychoses.⁵⁷⁻⁵⁸ The effects of adrenalin on psychoneurotic patients, especially in anxiety states, has been investigated.⁵⁹ This whole field has been reactivated by the development of new and accurate methods of measuring estrogens, androgens, gonadotropin and pregnanediol, and by the more current study of vaginal smears. Correlations have been drawn between various phases of the menstrual cycle and instinctual drives, types of phantasies and dream productions.⁶⁰ The relation between androgens, estrogenic substances and the clinical picture is reported in studies on homosexuality⁶¹⁻⁶² and hermaphroditism.⁶³

Of the various medical illnesses associated with endocrine disturbances, the most work has been done on hyperthyroidism (Graves's disease). As a result of studies in several large series of cases,⁶⁴⁻⁶⁶ it has been established that emotions associated with sudden fright or other psychic trauma frequently precede the onset of the illness. The appearance of exophthalmos and enlargement of the thyroid gland can appear within a few hours after the fright. Yet, according to Rahn,⁶⁶ these acute situations play a less important role in the precipitation of symptoms than do chronic worries or continuous anxiety. Little work has been done on the personality of patients with hyperthyroidism.⁶⁷

Rheumatoid Arthritis

In rheumatoid arthritis, one is dealing with a disease of unknown etiology characterized by exacerbations and remissions. Although the factors playing a role in the onset of the disease and its exacerbations are unknown, some authors have suggested that emotional disturbances, anxiety and worry play a significant role.⁶⁸ Cobb, Bauer and Whiting⁶⁹ found that in a series of 50 patients with typical rheumatoid arthritis, a significant relation between disturbing situations and the arthritis occurred in 60 per cent. The situations

found alone or in combination included financial distress, family difficulties, the loss of a parent or spouse and unfaithfulness of a married partner. The effect involved was usually that of worry. Further studies on the personality of these patients are still in progress.

Epilepsy

Among a long list of the factors that play a role in producing convulsions, Cobb⁷⁰ has listed emotional shock as one that is effective in producing vasoconstriction. He mentions that fright, anger and other strong emotions may cause pallor of the face and changes in circulation elsewhere in the body. In a study on 36 patients, Fremont-Smith⁷¹ found a direct relation between emotional tension and one or more of the major convulsions in two thirds of the cases. In several of the patients, all or nearly all the attacks had been immediately preceded by a strong emotion, usually that of fear, anger or frustration. Fremont-Smith was able to precipitate major or minor attacks in 8 of his patients by a discussion of the emotional difficulties. He concludes that, in many cases, the emotional tension acts as a precipitating factor for convulsive seizures, even though the patient may be unaware of this relation. Further studies on the unconscious mechanisms associated with fits have been reported by Kardiner.⁷²

Miscellaneous Diseases

The above summary deals briefly with some of the more complete studies in psychosomatic medicine. The literature contains reports dealing with many other varied conditions, such as anorexia nervosa,⁷³ glaucoma,⁷⁴ sciatica,⁷⁵ diabetes,⁷⁶ heart disease⁷⁷ and even fractures.⁷⁸ The development of greater interest in these problems has brought with it an ever-increasing number of observations in medicine and its specialties.

THErapy

Therapy in psychosomatic medicine is similar to that used in the treatment of the psychoneuroses. The symptom can be considered a reaction of the patient to a stimulus, which may be simple or complex, and may be known or unknown to him. Psychiatric therapy attempts to modify the stimulus or the person reacting to the stimulus, or both. In many cases, modification or removal of the stimulus—that is, changing of the situation or removal of the patient from the situation—has been of therapeutic value. Other psychotherapeutic efforts have been directed toward changing the patient to enable him to withstand any situation without the need for pathologic reactions. Two methods are employed for this purpose. The first

makes use of reassurance, suggestion, persuasion and even hypnosis, and as such is very closely bound up with the relation between the physician and the patient. The success or failure of this procedure goes hand in hand with the vicissitudes of the doctor-patient relation. The patient acquires no understanding of the factors involved, and his improvement remains associated with the magic power of the physician. The second means of change depends on the acquisition of insight and understanding on the part of the patient into the factors associated with the onset and exacerbation of the symptoms. This is accomplished by the use of either distributive analysis or psychoanalysis. In the former, the physician makes use of discussion that is based on the patient's modes of reaction and on his methods of handling difficult situations, especially those that seem to have a direct relation to the complaint. In psychoanalysis, emphasis is placed primarily on the uncovering and understanding of earlier modes of reaction, unknown to the patient. Therapeutic successes have been claimed by the proponents of all the therapeutic methods mentioned. As yet, no single approach has completely won the field. This fact alone suggests that considerably more effort must be expended in the future before a universally accepted therapy is developed.

SUMMARY

Psychosomatic medicine deals with medical disturbances in which situational and emotional factors play a role in either the precipitation or the exacerbation of symptoms. The situations are, as a rule, associated with the unpleasant feelings of fear, anxiety, guilt, resentment, frustration and longing. These illnesses are found in persons who have conflicts in reference to the expression of hostility and anger; most of them do not have the frank symptoms of the psychoneuroses. Many studies indicate that these are people with obsessive tendencies who tend to ruminate over their difficulties and find it impossible to resolve them on account of indecisions. It may be that these tendencies present constant stimuli to the autonomic nervous system and eventually lead to chronic irreversible reactions in the end organs, resulting in a pathologic process. The fact remains that therapy has lagged far behind the understanding of these problems. Yet, at the present stage of information, the only practical approach in many illnesses appears to be that of psychiatric therapy. This is especially true in situations in which medical therapy as such has failed or is still lacking. The inadequacy of psychotherapy in many cases is a challenge toward improving

present methods or toward developing new methods. The value of psychotherapy, promising as it seems at present, can be established only through carefully controlled studies. This is the task of the future.

THERAPEUTIC PROCEDURES IN PSYCHONEUROSIS*

ERICH LINDEMANN, M.D.†

BOSTON

PROCEDURES in the treatment of psychoneurotic conditions have not reached the simple level of known indications and expected results that has been attained in chemotherapy. Knowledge in the treatment of disease usually takes great strides forward when the disease can be reproduced in laboratory animals. Pavlov¹ was able to reproduce in dogs psychologic conflicts that made them behave like persons suffering from neuroses. He demonstrated pathologic nervousness and sleepiness. Liddell et al.² have similarly produced enduring derangements of behavior in sheep by a combination of stimuli and have treated them successfully with bromide medication. Some of their sheep developed a cardiac disorder shown by a rapid and irregular pulse brought on by stimuli that had no effect on normal animals. The animals were "conditioned," that is, taught to make discriminations between stimuli. When this process of discrimination is refined, — when it is made difficult by delay or interruptions, — neurotic behavior develops.

Maier^{3, 4} and Cook⁵ have carried out similar work with rats, and at a recent meeting of the American Psychiatric Association, Massermann⁶ presented evidence of neurotic behavior in cats that was produced by exposure to psychic trauma, which consisted in an annoying blast of air when, after having completed a task and opened a feedbox after a warning light had flashed, they were enjoying their reward and the satisfaction of their desire for food. He tried, and found successful, four different means of therapy: retraining by petting and reassurance, reinforcing and making inescap-

able the conflict situation, increasing the desire and strengthening the stimulus.

In human beings, the experimental production of neurosis and subsequent therapy have, for obvious reasons, not advanced so far, but laboratory research is stressed in clinics such as the Department of Psychiatry of the Massachusetts General Hospital.

A good many experiments were carried out years ago with hypnosis, by which it is possible to produce paralysis, anesthesia and changes in the skin capillaries and even minor changes in visceral functions (Charcot⁷ and Bernheim⁸). In addition, there are observations about events and their effect on the incidence of neuroses. The number of neurotic conditions during World War I increased vastly, whereas the number of schizophrenias remained the same, and the observations that are already being collected about the present war again throw interesting light on the effect of certain types of experiences on subsequent behavior. Mira,⁹ for example, mentioned first — and it was later restated by Miller,¹⁰ Gillespie¹¹ and Ross¹² — that the neuroses that might be expected to develop under the intense experiences of total war do not appear if the person has no possibility of securing refuge in a safe area but must instead remain in the situation. Furthermore, it has been found that separation of children from their families is much more effective in producing psychoneurotic disturbances than the experience of actual bombing.

None of these observations have up to now been systematic enough to suggest reliable systems of therapeutic procedures, and different psychiatrists still vary in their indications and choices of method. The powerful influx of a great deal of psychologic theory, which came about through the psycho-

*Presented at the annual meeting of the Massachusetts Medical Society Boston, May 27, 1942.

From the Department of Diseases of the Nervous System, Harvard Medical School, and the Department of Psychiatry, Massachusetts General Hospital.

†Associate in Psychiatry, Harvard Medical School, associate psychiatrist, Massachusetts General Hospital.

analytic school and the psychobiologic school, has led to a whole new jargon that has served only to alienate the medical man from the whole work of psychiatric treatment. He has been content to develop his own trial-and-error procedures or to refer to a psychiatrist all the problems that made him feel uncomfortable, stopping his interest in the patient at that point. Psychotherapy was, however, first practiced by medical men, and one of the greatest contributors to the understanding of hysteria, Charcot,⁷ made all his demonstrations in the medical clinic.

In this presentation, an attempt is made to present very simply the methods used in the Out Patient Department of the Massachusetts General Hospital, the indications under which they are applied, and the success obtained with them.

DIAGNOSIS

Diagnosis necessarily precedes a decision regarding therapeutic approach. At present, the neuroses are classified as reactive depression, anxiety neurosis, hysteria, obsessive neurosis and hypochondriasis. It will be noted that neurasthenia is not mentioned; this condition, often labeled neurocirculatory asthenia, has in many cases been found to be either a mild depression or a mild anxiety state, or an infectious or hormonal disease. The other conditions may be briefly described as follows:

Reactive depression. The patient does not necessarily cry. The outstanding symptoms are slowness, inability to concentrate, hopelessness and, often, bewilderment. Medical disorders that the patient may have at this time—for example, asthma and gastrointestinal disturbances—may be aggravated. Some practice is necessary to recognize this condition because the patient often succeeds in his effort to hide his distress.

Anxiety neurosis. The picture is one of acute attacks with marked visceral disturbances (heart action, respiration and gastrointestinal function) and an intense subjective distress referred to as fear or nervousness. The free interval between attacks may be one of exhaustion.

Hysteria. This term is perhaps the most abused in the nomenclature of the neuroses, any dramatic behavior being described as hysterical. Among psychiatrists, it means rather a condition in which one finds paralysis, weakness, aphonia, vomiting and bladder disturbance without a discoverable lesion. It is usually accompanied by a striking absence of anxiety, even though the patient, on study, is found to live in a distressing situation. These pseudoneurologic symptoms characterize a large group of war neuroses, but under peacetime conditions they are seen chiefly in women.¹³

Obsessive neurosis. This is usually well understood: preoccupation with foolish thoughts or the necessity of carrying out absurd or childish actions disturbs the patient.

Hypochondriasis. An important distinction must be made between anxiety neurosis, with evidence of genuine disturbance in the circulation and the visceral organs, and hypochondriasis, in which the patient complains of peculiar sensations in his body, such as changes in the shape and size of his head, and points them out to the physician as suggestive evidence of serious illness.

TREATMENT

After the condition with which one is dealing has been ascertained, the next step is to choose a suitable therapeutic procedure. The methods may be divided as follows: suggestion, especially hypnosis; reassurance; exploratory procedures in which one attempts to ascertain the distress under which the patient is expected to be laboring and tries to solve this problem with him; medicinal treatment; and, finally, guidance and care by social-service assistants. The exploratory procedures form by far the largest number. Because of the difficulties and skills involved in this method, it must often be delegated to a trained psychiatrist, who is familiar with the modes in which a person interacts to his environment, especially to other persons; yet it is essential for the general physician to know and use this procedure.

If a disorder is regarded as psychogenic it is considered to be due to conflicting stimuli arousing overwhelming emotions that the patient cannot handle with his own resources. The patient's symptoms, which to him represent disease, must be translated into a new context in which they will be recognized by both patient and psychiatrist as part of a disturbed emotional response to a difficult situation. Only if one succeeds in doing so, may the patient be successfully reassured about his illness, even though his difficulty may not be solved and even though he may feel upset. (Ross has given practical suggestions concerning how to do this successfully.¹²) Furthermore, only after the patient has found a solution of his predicament may he hope that his symptoms of anxiety and depression will disappear.

The successful completion of an exploratory procedure involves the discovery of a patient's predicament and a demonstration of its tangible solution. At first glance, this may appear a hopeless task. There is the necessity of winning over the patient for the psychiatric procedure and, after doing so, of making it possible for him to have free expression. Many failures occur at this point. Experience has shown that a number

of simple rules applying to the first interview may make all the difference between success and failure. The first of these is that the patient must believe that he is guaranteed reasonable privacy; this does not involve the privacy of a confessional. The patient is usually willing to waive this right if he knows how far his problems will be discussed and if he is assured of the bona fide interest of other listeners. Secondly, the patient must be assured that the physician has no moral bias and is willing to consider with him accounts even of events about which he feels very guilty or has broken taboos. Furthermore, the patient must be assured that the physician will not take advantage of him—that is, overrun him by authoritative advice when he would like to have an opportunity to make up his own mind. And, finally, the patient must have an opportunity to lead the way in the interview. This has led to a discarding of the ordinary systematic questioning in favor of a method by which material is collected in a somewhat erratic manner, following the lead of the patient and filling in the gaps as need be. Deutsch¹⁴ has described this procedure in great detail.

If these rules are observed and if one avoids compromising statements, not only may one succeed in obtaining the significant story of the patient's difficulty but also the solution may present itself to the patient without advice from the physician. In the presence of a trusted expert, the patient is likely to penetrate farther in his search for a solution, having stopped short at painful thoughts in his previous unaided ruminations.

It has been found desirable to separate this first step of the treatment into two phases: a brief preliminary interview, to get acquainted and to learn the essential complaint; and a second interview in which the patient is dealing with a known person with whom he may be confidential.

A frequent, false impression is that patients who have a large number of complaints and tell a great deal about their difficulties are the ones who benefit most. Much of the material may be quite insignificant. To understand which material is of consequence and which is not, some experience is needed in watching the patient's emotional response during the discussion, his hesitations and his labored efforts at communication. Apparently, only experiences that are described with some recurrence of emotion can be utilized for therapy. Of all the innumerable circumstances, it can be said that little turns out to have therapeutic moment except a situation that has aroused an overwhelming reaction of one of five major patterns of emotional response: grief in response to loss; anxiety in response to threat or temptation; rage in response to provocation; and the two

appetites, those of hunger for food and the need for sexual expression. The situation that aroused the emotion may be obvious or may become manifest only after considerable search. A person with hysteria of long duration may describe his life as free of stress and strain, and a person with an obvious anxiety neurosis may at first be completely unaware of any situation that should have aroused his rage or fear; yet it is always there, and if, after prolonged search, nothing along this line can be found, one is tempted to revoke the diagnosis and to consider seriously the presence of a structural or chemical disorder such as hyperthyroidism or a deficiency state.

The situation that arouses the abnormal response when once found may be strikingly simple and offer itself for easy remedy, as in the following case.

CASE 1. A 38-year-old fireman was referred 1½ years after he had fallen from a ladder and sustained minor hand injuries and a fracture of the right arm. Although the bone lesions had healed without defect, he was still complaining of pain in his arm and, in addition, had received compensation for nervous shock, symptoms of anxiety having developed about 4 weeks after the accident.

Exploration showed that this man had never had any serious illness, that he had in no way shown signs of "neurotic make-up," and he resented being questioned by a psychiatrist. It was discovered, however, that after the accident his superintendent had made arrangements to have him put on light duty and had given him a job as a telephone operator. Being accustomed to vigorous activity and to "showing off," he felt stifled. He then started to tell stories of former exploits and had to be repeatedly reprimanded by his superior. Being stalled from his usual activities, the patient became unduly irritated and had to refrain a good many times from outbursts of violence against the man who was guaranteeing him his compensation. Finally, the superintendent enclosed the telephone in a glass box, and thus effectively prevented him from any further verbal activity with his friends. It was then that the severe symptoms of anxiety developed.

With a knowledge of this state of affairs, it was obvious that the well-meaning rest cure had turned out to be the pathogenic agent and that winning the patient to attempts at renewed vigorous activity would be very likely to restore his equilibrium. He was advised to change his job and to apply for a position as probation officer, which he did successfully. At a subsequent visit 3 years later, he reported that he had been symptom free and that he had gladly given up his compensation for his new chance for enjoyable work.

Sudden, severe grief and sudden fright during accidents, as well as sudden prevention from the execution of an act of rage or an attempt to satisfy one's sexual urge, may be followed directly by a psychoneurosis. One is likelier to find, however, that a series of minor disturbances, to which the patient has not responded, may finally accumulate to such a degree that only a very violent or intense emotional reaction can offer adequate discharge.

CASE 2 A 27-year-old cranberry picker was referred 2½ years after sustaining a Pott's fracture of the right forearm while cranking a tractor. He complained of cramplike contractions of the muscles of the forearm, which led to a forced closure of his hand into a fist. Although his original fracture had healed, nervous symptoms had developed shortly after his return to work and he considered himself permanently disabled by this disorder.

Exploration showed that the cramp of the hand occurred only when the assistant superintendent was walking by, that the same assistant superintendent had ordered the patient, after hours, to crank the car an act that had produced the fracture and that this man had provoked him on innumerable occasions to violence. The patient had been unable to give in to these because he was on court parole for former brawls at the village tavern and had recently married a reformer wife who daily reminded him of his duty to keep his job for the sake of their child. He found to his own surprise that the cramp of his hand was really a fist about to be lunched against the hated assistant superintendent.

The symptom disappeared only after the company had given him a token advancement which somewhat improved his status in relation to the assistant superintendent.

Some such change in environment is often necessary to permit the patient to adjust himself without his symptoms. Even if the patient is willing to adjust himself to the situation again, a free saving device of some sort is necessary. Frequently, teamwork with a psychiatric social worker is indispensable to bring about this change which may be small indeed but which must exactly fit the patient's needs.

In the course of the exploration, it may become obvious that the patient habitually gets into situations that are very difficult for him to meet because of poor training or inadequate personality. If this is so, the simple exploration will not be satisfactory, and a more prolonged and effective method of altering the personality will be necessary. Patients with this type of condition must often be referred for psychoanalytic treatment. In severe conditions, such as hypochondriasis, it may be necessary to regard the patient as an object for care and guidance who may have to be looked after in a carefully planned family setting.

Fortunately, a large number of patients do not show any serious personality defect, but have developed their psychoneurotic inadequacy under the impact of a very difficult situation. If the situation is severe enough, the condition presented may constitute a psychiatric emergency, and special measures are indicated.

Under peacetime conditions, such measures are called for in the severe reactive depressions and the markedly incapacitating hysterical reactions with such symptoms as aphonia, paralyses and amnesia. In wartime these reactions occur in persons who witness violence and destruction and who should, with the greatest expediency, be re-

stored to their normal level of efficiency. For this purpose, a number of procedures have been developed, among which hypnosis finds its proper place. Hysterical monoplegias respond very well, as do states of anxiety after a severe traumatic experience. Hypnosis may be helped by the administration of sedatives, such as Pentobarbital and Sodium Amytal. Curiously enough, there is one other way of restoring such patients to proper functioning, by provoking in them an emotional reaction of the same degree as the previous traumatic reaction. This principle used to be applied by means of electric shocks, faradic current being employed, or by bringing the patient into frightening surroundings. These procedures have largely been abandoned. However, it may be advisable to use a chemical agent to produce a storm in the autonomic system.¹⁰ Thus, one may, to good advantage, give intramuscular injections of 20 to 25 mg of Mecholyl,¹ followed by appropriate commands for example, to make renewed efforts at using a paralyzed extremity and—even more important—to cease interfering, by undue contraction, with its proper functioning.

It is sometimes possible to use the emergency procedures as an opportunity for relieving the disturbing situations and for verbally expressing the emotional reaction connected with them. In this form, the so-called cathartic method initiated by Freud and Breuer has survived.

In most emergency procedures, however, one cannot get acquainted with the predicament. One pushes the patient back into a situation that once, at least, was intolerable for him. In war, this is inevitable, in peace, often enough, the situation has changed during the patient's hospital stay so that it has become more bearable.

However, in patients who are especially vulnerable,—that is, those who are especially easily aroused to overwhelming emotions,—one may have to use a procedure which confronts the person with the need for discussing repeatedly a disturbing situation that he has to meet. Freud discovered that recalling a painful experience is likely to bring with it a return of the emotion linked to this experience. This return is used in a skillful manner in psychoanalysis to 'desensitize' the patient and to steel him to cope with the ordinary occurrences that he will have to meet. Since some persons, owing to fear that they may have to meet difficult situations, have remained at an infantile level of emotional development and have missed a great many opportunities to strengthen and test their ability to withstand temptation and certain conflicts, psychotherapeutic procedures may well attain an educational value.

Numerous explorations have shown that a patient exposed to severe grief may temporarily be able to block his reaction in some manner. This reaction, however, may occur years later at the occasion of suffering a relatively innocuous loss. In other conditions, the emotional response may be delayed. It may also be distorted, and thus in grief a person who tries to extricate himself from his bondage to a deceased person may temporarily withdraw all his interest and may experience the world as unreal until his mourning is over.¹⁷ Since grief reactions, whether displaced or not, are usually self-limited, the task of the psychiatrist is often restricted to relieving the tension by mild sedation with Sodium Amytal or by stimulation with amphetamine (Benzedrine) sulfate.¹⁸ It may be pointed out that exploration can be performed only if the patient is not too much disturbed and if he is not too disinterested, and medical agents may be employed to maintain the most suitable level of emotional tension; thus, it is futile to discuss with a severely depressed patient the reason for his mourning.

One of the most striking depressive reactions, with agitation, insomnia, restlessness and hopelessness, is often found after surgery, particularly after pelvic operations in women, after tooth extractions and after eye operations.¹⁹ This reaction is not likely to occur before a free interval of four weeks, and may then go on for years, the patient being entirely unaware of the situation that has aroused the overwhelming emotion. Exploratory therapy tracing back the emotional response has led to the discovery that the rage response is the outstanding reaction. If the patient is helped to handle his unwarranted rage, readjustment occurs with surprising ease. A number of middle-aged women who were considered to suffer from melancholia have responded to this form of psychotherapy with enduring success after four or five interviews.

RESULTS

This review of methods may be augmented by a report about follow-up observations. Such observations are admittedly difficult because they depend on the goal that one has placed before oneself. Also, the reports of the patients and their families are often unreliable. One may, however, obtain a rough estimate if one agrees that treatment should be regarded as successful with patients who feel satisfied, are able to work and who are not handicapped in their social and sexual adjustment.²⁰ If they still have their symptoms but do not let them interfere with their work, they should be considered improved only. Everything else, for the purposes under discussion, has been considered failure.

Of 200 patients who were seen between October 1, 1937, and October 1, 1939, in the Psychiatric Out Patient Clinic of the Massachusetts General Hospital, and who were seen again a year after discharge, 162 were satisfied, and 38 considered the treatment a failure. These good results may partly be due to the fact that we selected patients who, experience had shown, would respond to treatment. In the progress of our work, we began to realize that the anxiety states, the reactive depressions and hysteria were suitable for the type of therapy available in our clinic.

The treatment of hypochondriasis proved unsuccessful in almost every case; obsessive neuroses improved only temporarily.

The patients with anxiety neuroses turned out much better. The explorative technic was used on all of them; some lost their symptoms after only one interview, and others, especially those who had phobias, had to have more than fifteen interviews. Several anxiety neuroses were temporarily relieved by amphetamine; some of them responded with a paradox reaction, becoming much worse.

The care of patients with depression was very successful, but it is suspected that some of the anxiety neuroses that had a depressive coloring improved not so much because of our efforts as because of the self-limiting character of a depressive reaction.

The patients with hysteria showed a mixed picture. Severe hysteria, with a history of longstanding infantilism and typical hysterical personality, does not respond well to general hospital psychotherapy. This seems to be the domain of the prolonged treatment and psychoanalysis, which may succeed with some patients when other methods fail, but even this procedure does not always guarantee success. Patients with hysteria who have undergone a large number of operations are also difficult; we have failed in almost every one of them. On the other hand, patients with limited hysterical symptoms, such as monoplegias, may lose their symptoms after one or two interviews or in response to one of the more forceful procedures, such as hypnosis or the use of Mecholyl.

If our findings are compared with those in other reports, it is noted that the recovery rate with systematic treatment varies but little from clinic to clinic, and that the percentages of recovery or marked improvement are reported as 70, 82 and 87.²¹ This looks very encouraging, but one must take into account the natural recovery rate of the psychoneuroses. Landis²² has collected statistical data from numerous hospital sources and has stated that 62 psychoneurotic patients out of every 100 are discharged from state hospitals within a

year. This, of course, does not mean that they are recovered or symptom free but rather that they have been able to be returned home. Controlled series of an adequate sort giving a natural history of the neuroses are not available as yet

* * *

It is possible to learn psychotherapy. Physicians in training witness interviews for about a month and then do explorative work themselves with patients, discussing each interview with an older man. From this experience, they become acquainted with the pitfalls of the methods and avoid the two most serious dangers of psychotherapy: getting involved in the patient's emotional reaction to the therapist and driving the patient into "acting out," in his social life, primitive reactions that may have been discussed in the interview. In consequence of these reactions, a poor psychiatrist may be as dangerous for a patient's social life as a poor surgeon for his physical life. A young physician who is not at all suited for psychotherapy very soon becomes bored with it. A certain amount of ability to listen and a capacity to let the other fellow have his say are prerequisites for this work.

In our clinic, in addition to young psychiatrists in apprenticeship, we also train a number of physicians whose primary interest is in medicine rather than in psychiatry but who want to be able to use psychotherapeutic methods intelligently in general practice and to learn to recognize cases that should be referred to a specialist for more intensive treatment.

At present, the war situation and the intensified requirements of industry, in which every loss of efficiency due to neurosis counts double, require

more than ever the psychotherapeutic efforts of the general practitioner. One of the most challenging problems is presented by the 8 to 11 out of every 100 selectees who are now being rejected because of psychiatric difficulties, for whom methods of rehabilitation are being sought.

CLINICAL FEATURES OF PANCREATIC LITHIASIS*

Report of Two Cases

ROBERT E. MOSS, M.D.,† AND EDWARD D. FREIS, M.D.‡

BOSTON

THE formation of stones in the pancreas has been recognized since 1667. The presence of stones in the pancreas of a patient with diabetes was first reported in 1788,¹ when a direct relation between pancreatic stones and diabetes mellitus was suggested. Further interest in this relation was aroused in 1901, when Opie² stated that stones may lead to atrophy of the pancreatic parenchyma, although the islet cells are not affected. In 1920, Barron³ pointed out that atrophy of the pancreas, resulting from long-continued obstruction of the ducts by stones, is not associated with diabetes mellitus provided that the islands of Langerhans remain intact. This observation served as the stimulus for the work that resulted in the discovery of insulin.¹

Despite the long history of the subject and its potential importance, it has generally been believed that pancreatic lithiasis is relatively rare. That this is not entirely true is shown by a few recent reports. In 1936, Mayo⁴ found 25 cases listed in the records of the Mayo Clinic, and in the next four years, Snell and Comfort,⁵ conducting a systematic search, discovered 18 additional cases. Opie,⁶ in 1500 necropsies, observed only 2 cases of pancreatic stones, and Dillon⁷ found only 2 among 2800 autopsy records. Lüdin,⁸ on the other hand, by very careful examination of each pancreas, noted 28 cases in a series of 542 autopsies. Warren⁹ reported a frequency of 3 cases in an autopsied series of 300 patients with diabetes. Smith and Bonis¹⁰ found, in the course of five months, 3 cases in a series of 240 roentgenologic examinations that included the pancreatic area. Finally, Rockwern and Snively¹ saw 2 cases within a month at the Cincinnati General Hospital, although only 3 had occurred among 7402 post-mortem examinations at that hospital in the preceding twelve years.

More and more cases are being diagnosed during life as the value of taking a flat film of the abdomen in patients with abdominal pain gains wider appreciation. It has been pointed out, however, that a barium meal can easily obscure the presence of pancreatic stones.¹ At the Boston City Hospital, the diagnosis was made in 3 cases from

1934 to 1941—at operation in 2 and at autopsy in 1. During 1941, 3 cases of pancreatic stones were recognized among 700 autopsies. Two additional cases were observed while on the wards of this hospital at the same time. The diagnosis in one rested on the roentgenogram; in the other, the roentgenographic findings were confirmed by palpation of the pancreas at laparotomy. Because we were able to study the pancreatic ferments of these patients before and after stimulation with Mecholyl (acetyl-beta-methylcholine chloride) and because few cases have been studied with the aid of such pancreatic stimulants as secretin and Mecholyl, we believe that our data warrant reporting.

To obtain the duodenal juice uncontaminated by gastric juice, the method described by Agren and Lagerlöf¹¹ was used, care being taken to place the tube under direct fluoroscopic control. Mecholyl was used to stimulate the external pancreatic secretion according to the method of Comfort and Osterberg.^{12, 13} Amylase activity was determined by the method of Agren and Lagerlöf,¹¹ and lipase activity by that of Crandall and Cherry.¹⁴

CASE REPORTS

CASE 1. Mrs. J. B., a 35-year-old woman, was admitted to the hospital in July, 1941, complaining of pains in the legs, with weakness and inability to walk, of 2 months' duration. For 3 months, she had experienced anorexia, nausea and vomiting, especially in the morning, associated with more or less constant, but not usually severe, pain in the midepigastrium and left upper quadrant of the abdomen.

The patient had been admitted to this hospital in 1937, complaining of pains and weakness in the legs for a month and of midabdominal pain and vomiting for 6 days. Physical examination at that time revealed emaciation, scaling skin over the forearms, a beefy red tongue, an enlarged, firm, nontender liver, bilateral foot drop, absent tendon reflexes, loss of position and vibration sense, and tenderness of the calves. On a high intake of vitamins, carbohydrate and protein, the patient gradually improved over a period of 15 weeks. The discharge diagnoses were as follows: chronic alcoholism; alcoholic gastritis; dietary and vitamin B complex deficiency, with emaciation; polyneuritis; stomatitis; fatty infiltration of the liver; and chronic pyelonephritis.

Physical examination at the second admission showed marked emaciation, a strong odor of alcohol, tremors of the hands, roughening and scaling of the skin, particularly over the dorsum of the hands and over the elbows, and multiple ecchymoses over the extremities. The tongue was smooth and red. The liver edge was firm, smooth and sharp, and was palpable 3 cm. below the costal margin. The abdomen was soft and extremely tender in the left

‡Senior intern, Fifth and Sixth Medical Services (Boston University), Boston City Hospital.

upper quadrant. The feet were plantar flexed and could not be voluntarily dorsiflexed. All tendon reflexes were absent. The calf muscles were tender to pressure. The blood pressure was 120/80.

The blood Hinton reaction was negative. The red cell count was 2,700,000 with a hemoglobin of 9.8 gm and the white cell count was 9600 with a normal differential. The urine showed a specific gravity of 1.070, no albumin, sugar, acetone or casts and 10 white blood cells per high power field in the centrifuged sediment. The nonprotein nitrogen of the blood was 27 mg per 100 cc. The serum protein was 5.2 gm per 100 cc. The icteric index was 15. Urobilinogen was present in the urine in dilutions ranging from 1:20 to 1:40. The bromsulphalein excretion test of liver function showed 100 per cent retention at 5 minutes and 50 per cent retention at 15 minutes.

Because the patient developed an acute exacerbation of her chronic pyelonephritis during the 2nd week, a flat film of the abdomen was taken. No renal calculus was noted but irregular areas of calcification were revealed that extended across the upper abdomen, both to the right and to the left of the midline, at the level of the first and second lumbar vertebrae. These areas followed the general outline of the head and body of the pancreas (Fig 1).

FIGURE 1 Case 1

This flat film of the upper abdomen shows many fine calculi in the tail, body and head of the pancreas.

and were later shown by gastrointestinal roentgenograms and by fluoroscopy during duodenal intubation to lie enclosed within the curve of the duodenum.

Determinations of the pancreatic enzymes, amylase and lipase, were carried out on two occasions, 19 days apart, by the methods noted above. The results are listed in Table 1. The serum lipase activity was 118 expressed in cubic centimeters of 0.05N sodium hydroxide (average activity ranges between 0.2 and 1.5 cc.). There was no diarrhea and examination of the stools stained with sudan III showed no increase in fat content. Glucose tolerance was determined with 100 gm of glucose by

mouth the values, expressed in milligrams of glucose per 100 cc of blood, were: fasting, 83; 1 hour, 265; 2 hours, 274 and 3 hours, 263.

On a regimen consisting of a high carbohydrate, high protein and low fat diet, supplemented by brewers' yeast, thiamine hydrochloride, niacin (nicotinic acid), Vegex

TABLE 1 Results of Continuous Drainage of Fasting Duodenal Juice for One Hour before and One Hour after Mecholyl

DATA	VOLUME cc	AMYLASE gm of maltose	LIPASE cc of 0.05 N NaOH
Normal values			
Before Mecholyl	10-120	6-250	0-10,000
After Mecholyl	10-180	30-500	2000-18,000
Case 1			
Before Mecholyl	31 >4	3.6-18.8	490-1310
After Mecholyl	55-73	9.5-40.2	1,90-2490
Case 2			
Before Mecholyl	78-80	2.2-27.5	960-17.0
After Mecholyl	0-120	8.3-39.8	1360-25.0

and ferrous sulfate orally in addition to 5 cc of crude liver extract intramuscularly twice weekly the patient slowly improved over a period of 2 months. The liver receded to the costal margin, although she did not receive lipocae. The bromsulphalein test eventually showed 80 per cent retention of the dye at 5 minutes and 30 per cent at 15 minutes. A biopsy of the liver, obtained at this time with the peritoneoscope, revealed only minimal traces of fat in the parenchymal cells with minimal increase in fibrous tissue. The red cell count rose to 4,400,000 at the time of discharge.

CASE 2 Mrs G K, a 57 year-old woman was admitted to the Third Surgical Service (Boston University) of the hospital in September, 1941, because of three attacks of severe, colicky, right upper-quadrant abdominal pain with associated vomiting during the preceding 4 years. Between attacks, she had suffered from abdominal bloating and gaseous eructations after meals, particularly after spicy or fatty foods, and occasional mild diarrhea. During the year before admission she had noted polyuria, polydipsia and a weight loss of 35 pounds. Because glycosuria and hypertension, as well as pancreatic lithiasis by roentgenogram, were discovered, the patient was transferred to the Fifth Medical Service for further study prior to operation.

Physical examination showed her to be obese and not acutely ill. The retinal arteries were narrow and tortuous, and the radial arteries were thickened. The heart was not remarkable. The blood pressure was 210/96. There was slight tenderness, but no spasm, in the right upper quadrant of the abdomen. The liver was not palpable.

The blood Hinton reaction was negative. The red-cell count was 4,500,000 with a hemoglobin of 12.2 gm (Sahli), and the white-cell count was 7000 with a normal differential. The urine showed a specific gravity of 1.035, no albumin, acetone or bile, an orange reduction with Benedict's solution, and 1 hyaline cast and 2 white blood cells per high power field in the centrifuged sediment. The nonprotein nitrogen of the blood was 30 mg per 100 cc., and the fasting blood sugar 143 mg. The icteric index was 5. Urobilinogen was present in the urine in a dilution of 1:16. The bromsulphalein excretion test showed 45 per cent retention at 5 minutes and 5 per cent retention at 15 minutes.

A Graham test showed poor filling of the gall bladder with dye and failure to empty after a fatty meal.

roentgenogram of the abdomen revealed several areas of calcification in the region of the head of the pancreas (Fig. 2).

Two determinations of pancreatic enzymes were performed 13 days apart. The results are recorded in Table 1. Stools stained with sudan III showed no excess of fat.

FIGURE 2. Case 2.

This lateral film of the upper abdomen shows two large calculi in the head of the pancreas.

While under observation, the patient had a severe attack of right-upper-quadrant colic, accompanied by fever and leukocytosis. The serum lipase during the attack was not elevated (0.73 cc. 0.05N sodium hydroxide).

After completion of studies and control of the diabetes by diet and 25 units of protamine zinc insulin daily, the patient was returned to the Third Surgical Service. Operation disclosed a large stone in the gall bladder, with a small stone and some gravel in the common bile duct. The liver appeared normal, and no biopsy was taken. The pancreas was not visualized. By palpation, however, it was considered to be atrophic, and several stones were easily palpable. No attempt was made to remove them.

DISCUSSION

The origin of pancreatic stones is not entirely clear. Because they consist of calcium carbonate and tribasic calcium phosphate, which are not present in normal pancreatic juice,⁵ and because bacteria have been found in them,¹⁵ it is generally assumed that infection of the pancreas causes an alteration in the juice, leading to the deposition of calcium salts.^{5, 15, 16} In addition, stasis of the secretions in the ducts appears to be necessary, as Lazarus¹⁷ found that stones could be produced in the pancreas of dogs only by a combination of stasis and infection. From this evidence, it has been inferred that pancreatitis and, possibly, cho-

lecystitis and cholelithiasis are the major predisposing causes of the disease. However, few cases have a history of previous attacks of pancreatitis. There was no conclusive evidence that either of the patients in the cases presented above had ever suffered from acute pancreatitis, although the mild abdominal pain and vomiting noted in Case 1 at the first admission could have had such a basis.

Many patients, however, show a coexisting cholelithiasis, although Snell and Comfort⁵ found only 3 in their series of 18 cases. One of our patients (Case 2) had associated cholecystitis and cholelithiasis; the other had no definite symptoms of gall-bladder disease and showed no cholesterol or calcium bilirubinate crystals in the "B" bile obtained by duodenal drainage. Although evidence of cholelithiasis or pancreatitis cannot be ascertained clinically in many cases, at post-mortem examination the pancreas is frequently the seat of an inflammatory process that may be evidenced only by fibrosis and cystic changes at the time of examination.

The clinical diagnosis, although difficult, is probably often missed because it is not thought of. Upper abdominal pain is usually the leading symptom, varying from mild distress to severe colic that resembles biliary colic. However, it is likelier to be referred to the left side of the abdomen and may radiate to the left side of the back, to the left costovertebral angle or to the left shoulder.⁵ Nausea and vomiting may be severe. Attacks seem to be induced by fatty foods, but are more frequently precipitated by alcoholic excesses than attacks of gallstone colic.¹⁵ *Fatty diarrhea* is perhaps the most characteristic sign of the disease, but it has been noted in no more than half the reported cases and may be intermittent, occurring only after an episode of colic.⁵ Enlargement of the liver may be another late sign of pancreatic damage. The work of Dragstedt et al.¹⁸ suggests that this results from fatty changes in the liver consequent to deficient production of lipocaic by the pancreas. Diabetes mellitus, actual or latent, accompanied by abdominal pain of obscure origin, should immediately point to the possible existence of this disease. Finally, icterus occasionally occurs in pancreatic lithiasis. If this syndrome is kept in mind and a flat film of the abdomen is obtained in suspected cases, the diagnosis should be made with greater frequency.

The chief difficulty in the clinical diagnosis of pancreatic stones lies in the frequent absence of unmistakable signs of pancreatic insufficiency. Coffey, Mann and Bollman¹⁹ have shown experimentally with dogs that gross alterations of digestion as manifested by steatorrhea and creatorrhea, occur only in the complete absence of the external pa-

creatic secretion from the intestine. Even small amounts of pancreatic tissue sufficed to maintain complete digestion in their animals. To facilitate the diagnosis of relative pancreatic insufficiency, when steatorrhea is absent, Agren and Lagerlof¹¹ using secretin, and Comfort and Osterberg,¹² using secretin and Mecholyl as pancreatic stimulants, describe methods for obtaining the external pancreatic secretion uncontaminated by gastric juice. The procedures give a roughly quantitative estimate of pancreatic output.

We used Mecholyl in studying the pancreatic enzyme production of our patients. Each patient was examined on two separate occasions, since we have found that one test may give misleading low results that cannot be duplicated later. Table 1 shows that the amylase and lipase contents of the duodenal juices of both patients were in the low normal range. In each case, there was a significant increase in enzyme content after stimulation with Mecholyl, the only exception being the first lipase determination in Case 2. The results of these tests indicate that some pancreatic damage was present, yet not enough to lead to gross steatorrhea. The conclusion appears legitimate that the damage was directly connected with the calculi present, which caused obstruction of the ducts with resulting atrophy of the acinar tissue. Lagerlof,¹⁰ Snell and Comfort,¹³ Smith and Bonis¹⁰ and Rockwern and Snively¹ found normal or low amounts of enzymes in their patients with pancreatic lithiasis.

Reference has already been made to the frequent finding of diabetes mellitus in association with pancreatic stones. Since the incidence of diabetes is greater in cases of longer standing, the implication is that it results from progressive destruction of the islets of Langerhans. However, it is remarkable that there may be no correlation between the degree of pancreatic damage and the severity of the diabetes. In fact, patients who appear to have extensive pancreatic destruction over a long period may show no sign of diabetes. Opie² commented on the case of a ninety year old man who had been in good health all his life despite the presence of steatorrhea for twenty years prior to his death; the patient had no symptoms or signs of diabetes; yet, at autopsy, the duct of Wirsung was completely blocked by a calculus, and the pancreas was almost wholly replaced by fat. Another man, who was 72 years old, had had fatty diarrhea for two years, but never had had glycosuria, the pancreas was entirely replaced by fat, with a large stone in the duct and smaller ones scattered throughout the gland. In a third case of pancreatic lithiasis, seen on the Third Medical Service of the Boston City Hospital before the cases presented above, the

patient was a known diabetic who had been controlled for a year by 15 units of protamine zinc insulin. He gradually failed, complaining of mid abdominal pain radiating into his left upper quadrant and back. The diabetes, during his final sojourn in the hospital, became less severe and was eventually controlled by 5 units of protamine zinc insulin daily. At autopsy, however, the pancreatic parenchyma was found to be about 95 per cent destroyed, being replaced by chronic inflammatory tissue and cystic, dilated ducts containing many irregular, rough stones.

So far as the enlarged liver that may be a late accompaniment of pancreatic lithiasis is concerned, we wish to point out that the patient in Case 1 showed a definitely enlarged liver, with decreased function of the bromsulfalein test. She was treated with a low fat, high-carbohydrate, high protein diet and a high vitamin intake, rather than with lipocac. Response to this regimen was quite satisfactory. The liver gradually receded to normal size, and a post treatment biopsy showed only minimal amounts of fat and fibrosis. We concluded that the hepatic enlargement in this case was not due to lipocac deficiency.

Although no attempt was made to remove the stones in either of our patients, surgery has frequently been employed successfully both to rid the patient of symptoms and to halt further destruction of the pancreas. Of 65 cases collected from the literature, 58 were treated surgically.¹⁴ Schmieden and Sebening²¹ call attention to 11 patients who were completely cured by removal of the stones. At the Mayo Clinic, when the diagnosis had been made sufficiently early, successful operations were performed.⁵ The danger of postoperative pancreatic fistulas has been largely overcome by improved surgical technique, and reactivation of the pancreatitis or peritonitis appears to be rare.

In the symptomatic treatment of the disease, the use of dried pancreatic juice to correct the symptoms of pancreatic insufficiency has been of value. Although the fatty liver in Case 1 did not require lipocac, Snell and Comfort found that it had a specific effect in at least 1 of their cases. The colic is usually treated with morphine, but ephedrine is worthy of a trial, since it diminishes pancreatic secretion. The primary treatment of this disease, however, is surgical.

SUMMARY

Recent reports agree that pancreatic lithiasis is not excessively rare. The clinical diagnosis is becoming more frequent as roentgenograms of the abdomen are more widely obtained in cases of obscure abdominal pain.

Two cases are reported in which the diagnosis was made during life by roentgenography and confirmed in 1 case at operation. The degree of pancreatic insufficiency was determined by examination of the enzyme activity of the duodenal contents after stimulation with Mecholyl. Lipase and amylase activity fell in the low normal range. Steatorrhea was not present. One patient had cholelithiasis and frank diabetes mellitus. The other had a decreased glucose tolerance and an enlarged liver that showed improvement without the use of lipocaic.

The essential features of pancreatic lithiasis are discussed.

MEDICAL PROGRESS

DISEASES OF THE THYROID GLAND

J. H. MEANS, M.D.*

BOSTON

SINCE my first report on this subject of three years ago,¹ a large amount of investigative work, both experimental and clinical, has been reported and must needs be digested. The large volume of such work is in part owing to the fact that many new approaches to the study of thyroid physiology, both normal and morbid, have recently become available.

For many years, one looked upon basal metabolic rate as the sole yardstick for measuring thyroid function. Then the determination of blood iodine levels made its appearance on the scene, and now such procedures as the measurement of thyrotropic hormone output in the urine, the collection of radioactive iodine by the thyroid, the effect of patients' serum upon the metabolism of test tissues, thyroid or other, the behavior of patients' thyroid when explanted in tissue culture and many other methods are available to him who would solve a hormonal riddle.

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress Annual*, Vol. III, 1942 (Springfield, Illinois: Charles C. Thomas Company, 1942. \$5.00).

*Jackson Professor of Clinical Medicine, Harvard University, chief, Medical Services, Massachusetts General Hospital.

A report on progress in diseases of the thyroid gland in this year 1942 may properly take its departure from the thyrotropic hormone of the anterior pituitary, or as it is convenient to call it, TSH (thyroid stimulating hormone), because this hormone still is a center of interest, and the discovery of how it acts on the thyroid cells may elucidate some of the morbid hormonal patterns encountered in thyroid diseases.

To the reader interested in being brought up to date on the now vast literature on TSH, the article of the Australian, Lambie,² can be most heartily recommended. Lambie reviews the literature, giving a bibliography of three hundred and nine titles, and also reports observations of his own and discusses the relation of the hormone in question to clinical syndromes. He draws the broad general conclusion that the ultimate stimulus to the thyroid is chemical, not nervous, but this does not mean that nervous influences may not impinge on the thyroid, nerve-borne from hypothalamus to pituitary, humorally from pituitary to thyroid. With this concept, I find myself in substantial agreement. It provides an explanation

for the paradox that whereas disturbed thyroid function may follow psychic trauma, experimental evidence is against any direct secretory innervation of the thyroid gland (Uotila¹)

That a hormonal balance exists between pituitary and thyroid was indicated in my previous review.⁴ Salter⁴ has given this the appropriate name of "pituitary thyroid axis," a beneficial axis in health, but sometimes leading to mischief in disease, like a certain other axis, which need not be mentioned. The evidence that the pituitary through its TSH drives the thyroid cells to increased activity is so abundantly proven as to need no further discussion, and DeRobertis⁵ has shown that changes in thyroid histology begin as early as fifteen minutes after the injection of TSH.

The evidence that the thyroid hormone inhibits the pituitary with respect to TSH secretion is also increasing (Reforzo Membrives,⁶⁻⁸ Uotila⁹ and Friedgood, Bevin and Uotila¹⁰). Reforzo Membrives, for example, claims not only that the pituitary glands of rats fed with thyroid fail to maintain the thyroid gland of pituitarectomized rats, but also that the thyroid glands of such rats showed an even more pronounced atrophy than those of pituitarectomized rats that had not received thyroid. In other words, the pituitary glands of rats long treated with thyroid had a depressing instead of a stimulating action on the thyroid glands of pituitarectomized rats.

The precise mode of action of TSH on the thyroid is now the subject of lively study. Collip¹¹ cites Eitel et al.¹² as having shown that TSH acts directly on the gland, not through an intermediary. Galli Mammi¹³ has confirmed this. Collip further cites Schneider and Widmann¹⁴ as having demonstrated that TSH will cause symptoms of thyrotoxicosis faster than thyroxine, which suggests that it cannot be considered merely as a liberator of thyroxine. However, the explanation for this relation may be that thyroxine after administration has to be altered in its molecular structure before becoming physiologically active, and that this process requires time, whereas the thyroid when stimulated by TSH puts out its hormone in more immediately available form.

Indeed, the whole problem of the form in which hormones are secreted and act on their end-organs is important but not well understood. Chow, Greep and van Dyke¹⁵ have treated various hormones with various enzymes and apparently have shown that when TSH is broken down enzymically below the protein level, it ceases to exert a hormonal effect. It is really unknown in what form thyroid hormone is carried in the blood and in what form it exerts its end-organ effect. It is stored in the follicle in a form which DeRobertis¹⁶ describes as an optically homogeneous,

highly viscous, refractile fluid (colloid). Its viscosity, he finds, diminishes after the injection of TSH and for a short period after the administration of potassium iodide. After a longer period on iodide, the viscosity of colloid increases. It is extremely interesting that DeRobertis was able to demonstrate in colloid obtained from single follicles a proteolytic enzyme which digests a gelatin substrate. This observation is interesting in connection with the work of Salter and Pearson,¹⁷ which showed that thyroid proteins can be synthesized enzymically. The thyroid hormone, however, does not appear to circulate as a protein, at least not as thyroglobulin, for Lerman,¹⁸ precipitating with thyroglobulin immune serum, could find none in the circulating blood in hyperthyroidism, hypothyroidism or euthyroidism. It may be broken down again enzymically between thyroid cell or follicle and end organ. Indeed, hormone physiology is rapidly entering the realm of enzyme chemistry.

TSH is also somewhat elusive when searched for in body fluids, but less so than thyroid hormone. Hertz and Oastler¹⁹ found evidence of thyrotropic activity in the blood and urine of myxedematous patients, but not in that of thyrotoxic or normal subjects. Rawson and Starr²⁰ demonstrated large quantities of TSH in the urine of totally thyroidectomized patients and failed to recover it from the urine of thyrotoxic ones. In the urine of normal young men, evidence of some thyrotropic activity was obtained, but much less than in that of those who had been thyroidectomized. Bastenie²¹ has also found thyrotropic activity in the urine in certain cases of myxedema. Robinson²² studied the bloods of patients with various sorts of thyroid disease, including myxedema and thyrotoxicosis, and was unable to demonstrate a thyrotropic effect in any of them. Collard, Mills, Rundle and Sharpey-Schafer²³ also searched for TSH in the blood. In normal subjects, they could find none, even after the injection of TSH at a time when the subjects were thyrotoxic from this injection. In thyrotoxicosis, they got positive assays in 4 out of 15 cases. Positive assays were also obtained in spontaneous and postoperative myxedema and in patients with severe proptosis and ophthalmoplegia, as discussed below. Loewer²⁴ injected large amounts of TSH into the blood stream of rabbits and was able to detect it for only thirty minutes after injection in the intact animal, but for much longer periods in the thyroidectomized one. Seidlin,²⁵ in a similar study, observed TSH in the urine of thyroidectomized guinea pigs that had been injected with large amounts of TSH, but could not recover it after injection into normal guinea pigs. Observa-

tions of this character raise the question whether the thyroid gland removes TSH from the blood stream or in some way inactivates it. Rawson, Sterne and Aub²⁶ reported that TSH, when exposed to tissue cultures of normal rabbit thyroid, lost its physiologic activity, but that no other tissue had this property except thymus and lymphatic tissue. These investigators further found that thyrotropic activity could be restored if the medium was heated in a sealed vessel at 100°C. for one hour. About 80 per cent of the original thyrotropic activity, which had been completely lost during exposure of the medium to thyroid tissue, could be recovered in this fashion. Furthermore, it was found that thyrotropic activity can be found in heated urine when it appears to be absent before heating. These observations, undoubtedly extremely important, indicate that the thyroid gland inactivates TSH, but does not remove it from the blood stream, and that somehow or other, in this process of inactivating TSH, the thyroid parenchyma receives a stimulus which causes it to become hyperplastic and to increase its secretion of thyroid hormone. This is essentially the conclusion also of Collard and his collaborators.²³

The morbid physiology as found in the thyrotoxicosis of Graves's disease may well be due not to an increased secretion of TSH by the pituitary, but to an increased sensitivity of the thyroid cells to TSH. The work of Stephens²⁷ supports such a view. He placed guinea pigs on starvation diets and observed that the thyroids of such animals became atrophic, but also that such thyroids were many times more sensitive to TSH than those of normally fed animals. These results suggest that the observations of Hertz and Means²⁸ and Andersen²⁹—that severe weight loss, with or without thyroid therapy, sometimes precipitates thyrotoxicosis—may also be explained on the basis of hypersensitivity of the thyroid to TSH action. Friedgood, Bevin and Uotila¹⁰ have also shown that the effect of TSH is significantly enhanced by adrenalin and by pilocarpine. They suggest that pilocarpine acts through the adrenal medulla and that adrenalin makes thyroid cells more sensitive to TSH. This brings to mind the once well-known Goetsch test.

The nature of the hormonal imbalance in various clinical syndromes has been studied by Galli-Mainini.³⁰ This investigator exposed normal guinea-pig thyroid to patients' serum in the Warburg apparatus and noted the effect on the oxygen absorption of the tissue (QO_2). For control, guinea-pig thyroid was exposed to normal human serum and the result was expressed as the percentage variation of the QO_2 of thyroid in patients' serum from that in normal serum. Such a procedure discloses whether the hormonal action

of a patient's serum is more or less thyroid-stimulating or thyroid-depressing than is that of a healthy person. Presumably, it shows whether thyrotropic activity of the pituitary or pituitary-depressant activity of the thyroid is in the ascendancy. Of course, the activity of antihormones of various sorts may enter the picture. In classic Graves's disease, Galli-Mainini found evidence of an excess, relative or absolute (presumably the latter because the basal metabolic rate is elevated), of thyroid hormone activity. By thyroidectomy this was corrected. There was an excess of thyrotropic activity in acromegaly and also in those peculiar cases of Graves's disease which Means, Hertz and Williams³¹ and Means³² have called Graves's disease with dissociation of thyrotoxicosis and ophthalmopathy, or a special ophthalmic type of Graves's disease. In untreated primary myxedema, there was an elevation in QO_2 , and in treated cases, there was a slight elevation in two and reduction in two others. This separation of Graves's disease into two types is further discussed below.

With regard to the finding in acromegaly, it is of interest that Davis³³ found the thyroid enlarged in 50 per cent of a series of 166 cases of acromegaly, and for contrast with this, we may recall that it has been known since 1851 that the pituitary is hyperplastic in cretinism (Nièpce³⁴) and since 1889 that it shows changes after thyroidectomy (Rogowitsch³⁵). In other words, in acromegaly, the enlarged pituitary may stimulate the thyroid; in hyperthyroidism, the lack of thyroid secretion may stimulate the pituitary.

There are other humoral agents than TSH which affect the function of the thyroid. Iodine is, of course, the time-honored one. The endocrine function of iodine has been made the subject of exhaustive critical review in two recent monographs (Elmer³⁶ and Salter⁴), to which the reader is enthusiastically referred. That iodine inhibits or counteracts the thyrotoxicosis induced by TSH administration, much as it does the spontaneous thyrotoxicosis of Graves's disease, is well established. Salter points out that such action may be either directly on the thyroid, on the anterior pituitary and its TSH, or on end organs peripherally. Salter and Lerman³⁷ have discussed the first of these as a mass action due to increased iodine concentration, which favors the storage of thyroid protein. Some writers, notably Marine,³⁸ believe that thyroid function is totally dependent on the pituitary, but the work of Chapman^{39, 40} indicates that the thyroid can respond with increase in parenchymal-cell height to iodine lack in pituitarectomized animals, and Vanderlaan, Vanderlaan and Logan,⁴¹ studying the QO_2 of animals to which

TSH was given with and without iodine, reached the conclusion that iodine acts directly to inhibit the metabolic activity of the thyroid. On the other hand, Chapman has found a physiologic action of iodine in animals without thyroids. This appeared in experiments in which it was shown that although the level of iodine intake does not affect the growth curves of intact animals, there was less weight loss in thyroidectomized animals on high iodine intakes than in those on low. Chapman suggested the possibility of the production of a throxinelike material in the tissues. In any event, it seems likely that the action of iodine on the pituitary-thyroid axis may be on more than one front.

As has become increasingly apparent recently, other chemical agents than iodine may exert a seemingly specific effect on the thyroid, or on the pituitary-thyroid axis. Since the work of Hunt⁴² in 1905 and of Chesney, Clawson and Webster⁴³ in 1928, it has been known that cyanides and vegetables containing these may be goitrogenic. Rawson, Hertz and Means⁴⁴ reported the case of a man who, after a year's treatment with potassium sulfocyanate for hypertension, rapidly developed the following weird syndrome: hyperplastic goiter with loud bruit, hypothyroidism, exophthalmos and blood iodine at the myxedema level. His thyroid promptly reverted to normal size, and his hypothyroidism disappeared merely on omission of sulfocyanate. The biopsy showed a wildly hyperplastic thyroid—hyperplastic but impotent, because his general state showed that he was suffering from a shortage of thyroid hormone. Kobacker⁴⁵ has reported a similar case, in which the picture went to that of full-blown myxedema. Kobacker's patient recovered on omission of sulfocyanate and exhibition of thyroid, but a year later, when sulfocyanate was resumed, the myxedema recurred. Dr. Herrman L. Blumgart tells me that a similar case has been observed at the Beth Israel Hospital, Boston, and from the Mayo Clinic (Fahlund⁴⁶) comes the report of a patient who developed what appeared to be acute thyroiditis as a result of sulfocyanate therapy for hypertension.

At the same time that these human cases in which sulfocyanates had had a significant effect on the thyroid gland were being studied, experimental work was appearing indicating that the sulfonamide drugs and other sulfur-containing substances may also cause thyroid hyperplasia (MacKenzie and MacKenzie,⁴⁷ Astwood⁴⁸ and Richter and Clisby⁴⁹). Thus, not only do cyanides and cyanates appear to be goitrogenic, but also a group of substances containing sulfur. The role of sulfur in the economy of the thyroid gland becomes interesting. One point of difference between

cyanide or cyanate thyroid hyperplasia and that caused by the sulfonamides is that the former is preventable by the administration of iodine while the latter is not preventable by this means.

How these agents work on the thyroid gland is of great interest but not settled. Do they act through TSH, directly on thyroid cells, or on the end organs of the thyroid hormone? The last-mentioned theory has been widely held but at the present writing seems unlikely. A group of New Zealanders has done significant work on this question (Kennedy and Purves,⁵⁰ Griesbach⁵¹ and Griesbach, Kennedy and Purves⁵²). These investigators caused goiter in rats by feeding seeds of the Brassica (cabbage) family of plants. The goitrogenic agent is presumably a cyanide of some sort. It was found that these seeds were highly goitrogenic, producing a clearly hyperplastic type of thyroid gland in intact animals, but had no such effect in hypophysectomized rats. Also, thyroid hyperplasia caused by feeding of the Brassica seed regressed after hypophysectomy, despite the continued administration of the seed. From these results, the authors concluded that the active principle of Brassica seeds cannot stimulate the thyroid gland directly, but requires the mediation of the thyrotropic hormone. They were also able to show that certain changes occur in the anterior pituitary glands of Brassica-fed rats—namely, a rapid increase in basophilic cells and a simultaneous loss of acidophilic cells. They concluded that the basophilic cells are the source of TSH. Sharpless and Hopson⁵³ had previously found quite similar changes in soybean-fed rats. Iodine or desiccated thyroid increased the proportion of acidophils and decreased the proportion of basophils, but only thyroid produced the normal percentage of basophils.

Whether any practical application to treatment will arise from these experiences with cyanides, cyanates, sulfonamides and so forth, it is impossible to say at present. In any event, it is worth the physician's while to know that sulfocyanate administration can cause goiter and hypothyroidism and that thyroid or iodine will prevent or control it; and also it can be said that the information is of great scientific interest, and may provide a new approach to the study of the pituitary-thyroid axis, or of the relation between the thyroid gland and its end organs, the cells of the body.

The relation between vitamins and thyroid and other endocrine activity is being given considerable attention. Carrière, Morel and Gineste⁵⁴ have studied the effect of both excess and deficiency of various vitamins on the thyroid gland in guinea pigs. An excess of either vitamin A or C was

found to inhibit the gland, an excess of vitamin B to stimulate and an excess of vitamin D still further to stimulate. It was concluded that vitamins A and C may be helpful in hyperthyroidism, but that vitamin D and heliotherapy are contraindicated. The action of vitamin B in these experiments is of academic interest only because there is abundant evidence that this vitamin is helpful in the treatment of thyrotoxicosis (Means, Hertz and Lerman,⁵⁵ Frazier, Brown and Vars⁵⁶ and Bickel⁵⁷). Wohl and Feldman⁵⁸ suggest that hyperthyroidism destroys and depletes vitamin A reserves in the body. This is evidenced by pathologic dark adaption in 18 out of 20 patients with thyrotoxicosis. Azerad⁵⁹ also gathered evidence of the same sort and concluded that vitamin A may be useful in thyrotoxicosis.

Thyroid-gonad interrelations also awake some interest. Nathanson, Brues and Rawson⁶⁰ found that testosterone propionate is capable of stimulating the thyroid and parathyroid glands of the intact immature female rat. It is not clear whether this is a direct effect or one routed through the pituitary gland; the latter was thought more likely.

Estrogenic substances have been tried in the treatment of thyrotoxicosis, with, on the whole, conflicting results. Robinson⁶¹ treated 5 patients with primary Graves's disease and 2 with toxic adenoma with massive doses of Progynon B, without success except in a menopausal case in which the relation of the result to therapy given was uncertain. Goldman, Goldman and Kurzrok,⁶² on the other hand, treated 8 women with hyperthyroidism with large doses of Progynon B. Five of these patients were at the menopause, and all showed improvement. These authors conclude that some cases of menopausal thyrotoxicosis respond favorably to treatment with estrogenic hormone.

In the radioactive iodine approach to thyroid physiology and therapeutics, progress continues to be made. After studying the uptake of iodine by the thyroid gland under a variety of experimental and clinical conditions, Hertz and Roberts⁶³ have recently made use of radioactive iodine in the treatment of thyrotoxicosis, with some encouraging results. Hamilton and Lawrence⁶⁴ have also reported results in 3 cases. Since the original paper on the use of radio-active iodine in the study of thyroid physiology by Hertz, Roberts and Evans,⁶⁵ a considerable literature has accumulated. Hamilton, Soley and Eichorn⁶⁶ have introduced the autoradiogram, by which they show, as would be expected, that hyperplastic thyroid tissue has the greatest ability to concentrate iodine. Perlman, Chaikoff and Morton⁶⁷ have studied iodine uptake by various tissues and find that thyroid tissue re-

tains over a hundred times as much as others. This is a confirmation of the observations by Hertz, Roberts, Means and Evans.⁶⁸ The authors conclude that the thyroid gland retains iodine selectively, whereas its escape from other tissues is by diffusion only. They also showed that thyroxine is rapidly formed in the thyroid glands of both rats and sheep, but that a larger portion of administered iodine is found in the form of diiodotyrosin than thyroxine. Leblond and Sue⁶⁹ have found that TSH augments the power of the thyroid gland to fix iodine. The ensemble of their results, they conclude, on animals hypophysectomized or treated with TSH shows that this hormone controls the metabolism of iodine in the thyroid. In view of the work of Chapman,^{39, 40} this statement may need some revision. In a later study, Mann, Leblond and Warren⁷⁰ gathered evidence which indicates that iodine does not exist as such in the noniodized gland of the dog. Inorganic iodine does not appear to be the major source of the iodine of diiodotyrosin. Therefore, the conversion of radioactive iodine into diiodotyrosin must take place at the cell membrane unless it arises elsewhere in the body and is secondarily fixed as such in the thyroid cells—a possibility that the authors consider unlikely. Diiodotyrosin appears to be the natural precursor of thyroxine. The radioactive iodine approach has even been applied to comparative physiology, Gorbman and Creaser⁷¹ having shown that iodine is specifically localized in the endostyle of lamprey larvae. This organ, therefore, must be a primordial thyroid gland.

The methods of determining the iodine levels of the blood have been improved to the point of great clinical usefulness. The information to be got is analogous to that yielded by the basal metabolic rates. Salter, Bassett and Sappington,⁷² for example, studying the relation of clinical symptoms, basal metabolic rate and blood iodine, found that in 71 cases in which the clinical impression of thyroid status—that is, hyperthyroid, euthyroid or hypothyroid—and the basal metabolic rate were in agreement, there was also a high degree of agreement between basal metabolic rate and the protein-bound iodine in the blood. In the 29 cases in which there was no such agreement, the blood iodine gave a better agreement with the clinical impression, and the authors therefore regard it as a better yardstick of thyroid function than the basal metabolic rate. It is, however, harder to do and more costly. Bassett, Coons and Salter,⁷³ studying the naturally occurring iodine fractions of the blood and their clinical behavior, divided these into T iodine (thyroxinelike), D iodine (diiodotyrosin-like), P iodine (protein bound) and

I iodine (inorganic). The ratio, T/P, gave the following results in different states of thyroid function: myxedema, 0.19, normal, 0.73, and hyperthyroidism, 0.76, 0.71 and 0.76. Thus, except in myxedema, in which little or no thyroxine circulates in the blood, the P fraction appears to be a practical and useful method for clinical investigation and routine diagnosis, because it affords at least a roughly quantitative measurement of the circulating thyroid hormone.

The special ophthalmologic problems of Graves's disease hinted at in my previous report¹ have aroused much interest in the intervening years. Indeed, one might almost say that a new specialty of endocrinologic ophthalmology is a borning, and rightly so, for neither the endocrinologists nor the ophthalmologists seem to know much about this peculiar field. However, it is untrue to suggest that the subject is a new one. Marine³³ states that the experimental study of exophthalmos began as early as 1858 with the work of Muller,⁷⁴ and Gley,⁵ in 1910, reported that animals could develop exophthalmos following thyroidectomy. In discussion of Gley's paper, Poncet⁷⁶ remarked that the mechanism in Basedow's (Graves's) disease seems to result from a dysthyroidism amounting to a more or less severe poisoning. If then Gley had removed the entire thyroid parathyroid apparatus, suggested Poncet, why might not there have been a vicarious exophthalmos producing action exerted by some other organ, perhaps the pituitary? Gley did not appear to value Poncet's suggestion very highly but it looks at present as though Poncet had made a very prophetic remark, and that Gley had missed the significance of his own observations.

The pathogenesis of exophthalmos has been studied both experimentally and clinically by many investigators, and it can be taken as well established as shown in 1932 by Loeb and Friedman⁷⁷ and in 1933 by Marine and Rosen,⁷⁸ that exophthalmos can be produced by the administration of anterior pituitary, and also that thyroidectomy enhances such action. Marine⁷⁹ further claims that both the adrenal glands and the gonads are involved in the endocrine hook up. Certainly, it appears that progressive exophthalmos is more easily produced experimentally in males, and although Graves's disease is more common in women, progressive or malignant exophthalmos is relatively more frequent in men. Other reports of experimental production of exophthalmos with anterior pituitary are numerous (Friedgood,⁸⁰ Smelser,⁸¹ Paulson⁸² and Aird⁸³). Also well established now is the fact that in human Graves's disease, exophthalmos may become aggravated and may take on a progressive course following thyroidectomy. Among recent papers on this subject are those of Daniels,⁸⁴ del

Castillo and Reforzo Membrives,⁸⁵ Jensen,⁸⁶ Means Hertz and Williams⁸¹ and Soley.⁸⁷

The pathology of progressive exophthalmos in Graves's disease seems to be established as one chiefly of swelling of the orbital muscles, with lymphoid infiltration, but also edema of the entire contents of the orbit (Dudgeon and Urquhart,⁸⁸ Moore,⁸⁹ Naffziger,⁹⁰ Duthie⁹¹ and Smelser⁹²). The sequence of events in its development has been reconstructed by Galli Mainini.⁹³

From the practical side, the important point is that there are certain patients with Graves's disease in whom thyroidectomy is contraindicated. They are to be recognized (Means, Hertz and Williams⁸¹ and Means⁸²) by the fact that their eye complaints and signs are more striking than their thyrotoxic ones, and that they make a superstandard response to iodine, often to minus levels of basal metabolic rate. Their thyrotoxicosis is usually easily handled by iodine alone, and when this is not sufficient, x-ray treatment to the thyroid may be used. For the eye condition, in which hypofunction of the anterior pituitary—relative if not absolute—is probably a factor, thyroid may be given (on the theory that it depresses the pituitary), either alone or in combination with iodine. Haines⁹⁴ states that iodine and thyroid together have been used at the Mayo Clinic in cases of Graves's disease with severe ophthalmopathy and a low basal metabolic rate since 1922. Results are variable, but the treatment is worth trying, when it is insufficient, irradiation of the orbits or of the pituitary gland may be tried.

The use of thyroid for any purpose in the treatment of Graves's disease demands explanation. In addition to the indication mentioned above, Rienhoff⁹⁵ has used it for a different purpose, namely, to cause atrophy or prevent regeneration of the fragment left behind after subtotal thyroidectomy. For this purpose, he gives thyroid preoperatively to thyrotoxic patients and finds that no aggravation of symptoms results. In passing, we may note that Silex,⁹⁶ in 1896, claimed to have cured a case of Basedow's (Graves's) disease with thyroid tablets. Related to these observations of Rienhoff is in that it also represents a suppression of thyroid activity by the administration of thyroid hormone, is the work of Farquharson and Squires,⁹⁷ in which it is shown that long-continued exhibition of thyroid to patients with so-called "nonmyxedematous hypometabolism" causes a depression in thyroid gland activity manifested by the fall of the basal metabolic rate on the omission of thyroid, to a lower level than the original one. The thyroid glands of these patients became indolent under the continued artificial supply of thyroid hormone, or perhaps their pituitary glands became indolent.

and no longer stimulated their thyroid glands. Of course, the development of an antithyroid hormone during thyroid administration is another possible but, I believe, unlikely explanation of these results.

The question of liver involvement in thyrotoxicosis is always an important one. Haines, Magath and Power⁹⁸ find that the excretion of hippuric acid is reduced in a significant number of cases, an indication that the liver is often functionally disturbed. McIver and Winter⁹⁹ have shown experimentally that the administration of thyroxine increases the vulnerability of the liver to chloroform but, somewhat surprisingly, that this is not a result of glycogen depletion.

Of the treatment of Graves's disease in general, it is interesting that in the Thyroid Clinic of the Massachusetts General Hospital we have come full circle in a quarter century.¹⁰⁰ In the years 1919-1922, half the cases were treated by nonsurgical methods. In 1932-1935, surgery was employed in 95 per cent. In 1942, half surgical, half nonsurgical procedures are being employed. The nonsurgical cases include the special ophthalmopathic type in which we believe thyroidectomy contraindicated, and a variety of others treated successfully by iodine alone, radioactive iodine or x-ray.

In the field of myxedema, I should like to stress particularly the importance of distinguishing between the primary thyroid form and the pituitary form with secondary hypothyroidism (Castleman and Hertz,¹⁰¹ Means, Hertz and Lerman¹⁰² and Lerman and Stebbins¹⁰³). The practical reason is that the indications for treatment are different. Thyroid alone totally relieves the former; it is not alone sufficient in the latter, but must be supplemented by other endocrine agents and salt. The salt is used as a preventive to adrenocortical insufficiency, which may be induced by thyroid alone. Thompson and his co-workers¹⁰⁴ have shown that the administration of TSH has no effect in human myxedema. This is what one would expect. They¹⁰⁵ have also shown quantitatively the relative ineffectiveness of thyroxine by mouth. Talbot et al.¹⁰⁶ have demonstrated that the level of serum phosphatase of infants and children with untreated hypothyroidism is abnormally low. It is restored to normal by adequate thyroid therapy. The phosphatase level can be used as a measure of thyroid deficiency.

Angina pectoris, which appears in myxedema on treatment with thyroid, is well known and is one of the complications to guard against in the inauguration of substitution therapy. Mussio Fournier and Fischer¹⁰⁷ have shown that another type occurs while the patient is myxedematous and disappears on thyroid therapy.

What may be called a positively charming piece of research on hypothyroidism has been done by Richter,¹⁰⁸ who placed rats in cages and supplied them with rolls of paper from which they could tear off bits to make nests. The amount used in nest building was measured and found very constant: thyroidectomized rats used much more paper than normal ones. Recall the human being with myxedema who requires much more bed-clothing!

Of malignant disease of the thyroid, space permits me to say nothing. Perhaps, after all, this is not a thyroid but a cancer problem.

Of curiosities in the thyroid field, I may mention the report of an echinococcus cyst of the thyroid by Blum, Boquet and Hantcheff¹⁰⁹ and one of hemochromatosis of the thyroid gland by Graham and Mallory.¹¹⁰

In the field of surgery of the thyroid, there appears to be nothing radically new. The surgeon's point of view is well stated in a recent study by Albright and Clute.¹¹¹ It differs, of necessity, somewhat from that of the physician because the surgeon thinks in terms of operations, whereas the physician thinks in terms of patients. Certain patients will doubtless have to have portions of their thyroid glands removed for many years to come. Occasionally, they may require total thyroidectomy, and when such procedures are necessary, a high surgical skill is available. But removal is not always the best way to bring about restoration to health in the person with a diseased thyroid, nor are the results of removal always perfect. I shall close this report with the prophecy that surgery will be used less and less in this field as the endocrinology becomes better understood.

CASE RECORDS OF THE
MASSACHUSETTS GENERAL HOSPITALANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 28421

PRESENTATION OF CASE

A sixty-nine-year-old physician was admitted because of severe chest pain.

Three years previously, the patient, who was known to have had hypertension for at least ten years, had suffered with occasional attacks of dyspnea accompanied by a feeling of faintness, which required admission to a hospital. After enforced rest, he recovered and was able to get about, enjoying only limited activity. However, in spite of this limitation of activity, he noticed occasional attacks of substernal oppression, particularly on exertion. During the next two years he again entered a hospital twice for brief periods of study and rest. He carried on very little practice during this time. Three months previously, the attacks of substernal discomfort became more severe and occurred more frequently, and two months later, he entered a community hospital. While there, he had more and more trouble of this same sort, even while resting in bed. During the fourth week of his hospital stay, after a good night and soon after waking, he was seized with a very severe anterior chest pain radiating down both arms, down his back and into both legs with great intensity. The leg pain was said to have been similar to that of sciatica. This attack continued more than twelve hours in spite of the repeated administration of Dilaudid.

Physical examination showed a well developed, obese man who was obviously acutely ill. He was slightly cyanotic and dyspneic. Breathing was irregular and of Cheyne-Stokes type. The examination of the heart revealed the maximum apical impulse 12 cm. to the left of the midsternal line in the sixth intercostal space. The retromammary dullness was not increased. The heart sounds were of mediocre quality. The rhythm was regular. The pulmonic second sound was sharp. No murmurs were audible. There was some increased filling of the neck veins. The radial pulse was thready, and the vessel wall was soft; no pulse deficit was noted. The lungs were normal. The abdomen was distended. No masses were felt, and no tenderness of the liver edge could be elic-

ited. There was a slight amount of pitting edema over both ankles. No pulse was felt in the vessels of the feet or in the groin. There was no clubbing of the fingers or toes.

The blood pressure was 150 systolic, 115 diastolic. A slight alternation of the pulse was noted when the blood pressure cuff was at this systolic pressure. The pulse rate was 110.

An electrocardiogram was said to have shown sinoauricular tachycardia. The cardiac rate was 120. The PR interval was 0.25 second. The T waves were low in Leads 1, 2 and 3 and of fair amplitude in Lead 4.

The patient did poorly, continued with the same picture of pain, shortness of breath and cyanosis and died four days later, in spite of supportive therapy in the form of oxygen and sedatives.

DIFFERENTIAL DIAGNOSIS

DR FRANCIS R. DIEUVAIDE. Although the record ed examination of the heart is not entirely clear so far as its size is concerned, I take it to mean enlargement, probably downward and outward, of moderate degree. The PR interval in the electrocardiogram was considerably more than it should have been. At the same time, there was no bradycardia, but a tachycardia. The patient was obese and was known to have had hypertension. These are general data of some importance.

To proceed at once to the final major episode, among the things one might consider is a large arterial embolus. That is suggested especially by the absence of pulsation in the feet and groin and perhaps might have fitted in with the attack of severe pain. But it seems very unlikely in this case. It offers no explanation of the preceding attack of pain or of the previous history of the patient. Furthermore there was no source for such an embolus. Large arterial emboli usually occur in cases of mitral valvular disease. This patient had no evidence of valvular disease, endocarditis or auricular fibrillation. It is true he had been in bed off and on. One might think of the possibility of his having a thrombus in a leg vein and an embolus from that, but to use that possibility one would have to suppose a "paradoxical embolus," which I cannot do.

The early story raises the question whether the patient had syphilitic aortitis. There is no report of a blood test for syphilis, which would not be decisive but which one would naturally like to have. Perhaps we might assume it had been done and was negative. There were no signs of aortic regurgitation, but we must remember, of course, that a patient may have a huge sacular aneurysm of the aorta without aortic regurgitation. There was no evidence of enlargement of the aorta on

physical examination, and we have no information about any x-ray picture of the chest. There was no physical sign of an aneurysm. On the other hand, one has to remember that an aneurysm at the back of the arch of the aorta or of the descending thoracic aorta would be extremely difficult to pick up on physical examination. Sometimes these are missed on x-ray examination. We know, in this connection, that the patient had hypertensive disease, which means that, if he had syphilitic arterial disease in addition, he had two diseases. I exclude syphilitic aortitis on the basis of the evidence that we have.

Then the question arises whether the patient had a dissecting aneurysm. It might, perhaps, be better if we had another name for that condition to separate it from saccular aneurysm, but the name seems to be fixed. The patient's age fits in satisfactorily enough. Most patients with dissecting aneurysm are between fifty and sixty, but I do not take the limits too seriously. The patient was known to have hypertension, which fits well with the diagnosis of dissecting aneurysm. The description of the major attack of pain is also compatible. We may guess that, soon after waking in the morning, the patient was not very active, so that there was no particular connection between the pain and activity, which is typical for the onset of dissection. Pain first occurred in the front of the chest and radiated down both arms. Radiation down the arms is much commoner with acute coronary occlusion than with dissecting aneurysm, but many cases of coronary occlusion have no radiation into the arms and a certain number of cases of dissecting aneurysm do have such radiation. The pain also went down the back and into both legs. I should take the radiation into the legs to be fairly strong evidence of dissection. The absence of pulsation in the groins and in the feet also fits in with dissection. We are not told the condition of the patient's legs and feet, except that they were pulseless. We do not know whether any neurologic changes or any limitation of motion existed.

DR. TRACY B. MALLORY: There were none.

DR. DIEUAIDE: It is an interesting fact that a group of patients with dissecting aneurysm, as well as patients with other aneurysms of the descending aorta, have various neurologic changes in the legs, which are very important diagnostically when they are present.

If we think the patient had a dissection I suppose the question might be raised whether he also had an old dissection, because we know that there are a few patients who have an almost silent dissection with formation of a second aorta and subsequent further dissection and rupture. We have

no particular reason to think that occurred in this patient, although I do not believe it is out of the question. The question might also be raised whether he is one of the few patients who have dissection with coarctation of the aorta. We have no good evidence of that. He had hypertension in his arms; we do not know the popliteal blood pressure.

Then we must, of course, consider the diagnosis that I mentioned first—coronary occlusion with myocardial infarction. The early part of the history very strongly suggests coronary sclerosis. These repeated attacks, rather severe in nature, are suggestive of coronary insufficiency. The major attack, following which the patient died, does not resemble the ordinary development of myocardial infarction. The disappearance of the pulsation in the legs has no particular relation to myocardial infarction, unless it were a later event, following embolism. The patient did not show the picture of shock following this accident, at least according to the data we have. The blood pressure was well maintained. In the case of an infarct followed shortly by death, the blood pressure usually falls markedly.

Then we come to the electrocardiogram, which is troublesome. It showed increased auriculoventricular conduction time (0.25 second). No statement is made regarding digitalis, which is an important omission.

DR. PAUL D. WHITE: That is an error. He had been fully digitalized because of the dyspnea—for some years, as a matter of fact.

DR. DIEUAIDE: He was digitalized, then, and had been regularly, so that although changes in the auriculoventricular conduction time are common in myocardial infarction, we ought to place this finding aside. It would be remarkable, however, to have increased auriculoventricular conduction time as the only electrocardiographic evidence of infarction.

DR. WHITE: May I correct my last statement? I find that, although he had had much digitalis in the past, he had had none within the last week or two. So there was not enough digitalis in his system to produce the delay in auriculoventricular conduction.

DR. DIEUAIDE: That makes this finding more important. Perhaps Dr. White would like to discuss it. Since digitalization is not the explanation, we must consider the other possibilities. The patient may have had a chronically prolonged conduction time as a part of arteriosclerotic heart disease. We do not know about that because we have no previous electrocardiogram. Myocardial infarction, however, seems to be a better explana-

tion At any rate, we cannot connect this finding with a dissecting aneurysm.

DR. WHITE: From my experience I should say the reverse, namely, that heart block, either auriculoventricular or intraventricular (bundle branch), is much more often evidence of chronic coronary heart disease than of an acute process. In most persons, heart block is discovered either accidentally by electrocardiograms or as a result of symptoms of faintness and not following a typical episode of acute myocardial infarction, whereas the great majority of patients who have perfectly classic attacks of acute myocardial infarction have no heart block at all or only for a few days, in the rare cases of posterior wall infarction. There are exceptions, but that is the rule.

DR. DIEUAIDE: Do you favor infarction rather than dissection here?

DR. WHITE: I should say that coronary heart disease, but not acute infarction, was one of the conditions present. The changes in the ST segments and T waves are more important than the presence of block with respect to an acute episode.

DR. DIEUAIDE: Concerning the rest of the electrocardiogram, the fact that the T waves were low in normal leads and not in Lead 4 gives us no help.

DR. WHITE: This record was taken about six hours after the attack.

DR. DIEUAIDE: In summary, my interpretation of the case is that the patient, who had hypertension, probably did have coronary sclerosis and that he suffered from chronic impairment of his myocardial reserve. I interpret the major accident to be a dissection of the thoracic aorta that extended down into the abdominal aorta.

DR. MALLORY: Would you like to speculate on the mechanism by which the dissection might have caused death.

DR. DIEUAIDE: You raise the question because of the long interval?

DR. MALLORY: Yes, in part. Dissection per se is not a lethal condition. Patients have had dissection sometimes with and sometimes without symptoms and have lived many years afterward.

DR. DIEUAIDE: I do not think I can offer a good explanation for it.

DR. WHITE: May I ask Dr. Dieuaide if he thinks a likely explanation of death might have been the final rupture of the adventitia of the aorta, with hemorrhage into one of the serous cavities?

DR. DIEUAIDE: Accepting the diagnosis, I should think that would be a natural end, but we have no data that describe what the termination was like.

DR. WHITE: It was sudden.

DR. MALLORY: The blood pressure strikes me as unusual—a very high diastolic pressure and an extremely low pulse pressure.

DR. WHITE: In both coronary occlusion and dissection of the aorta, I have seen high blood pressure maintained. I have noted hypertension in some cases only during coronary thrombosis, doubtless as the result of pain, thus the response of different individuals varies greatly. In this case, the maintenance of high blood pressure favors dissection of the aorta rather than myocardial infarct, as you have intimated.

CLINICAL DIAGNOSES

Hypertensive and coronary heart disease
Dissecting aortic aneurysm
Angina pectoris
Congestive failure.

DR. DIEUAIDE'S DIAGNOSES

Dissecting aneurysm of thoracic and abdominal aorta.
Hypertension.
Coronary sclerosis
Myocardial infarction, old

ANATOMICAL DIAGNOSES

Dissecting aneurysm of aorta and great vessels of neck
Cardiac tamponade
Arteriosclerosis coronary, moderate, and aortic, marked
Infarcts of kidneys, partial and complete

PATHOLOGICAL DISCUSSION

DR. MALLORY: This man did have a dissection of the aorta. We found a tear in the intima about 2 cm. above the aortic valve. From that point, dissection had occurred backward to the annularis of the aortic valve and forward almost down to the iliac arteries. One rather unusual feature of the case was that there was an extensive dissection of the carotid and innominate arteries. It is not uncommon for dissection to pass the bifurcation of the aorta and to extend several centimeters down the iliacs. There was little involvement of the iliacs here, whereas in contrast the dissection of the vessels of the neck was very marked. I think it is conceivable that, with a little closer observation, some symptoms might have been made out to indicate that, but there is nothing in the record.

The terminal episode was rupture of the outer layer of the aorta into the pericardium, with death from cardiac tamponade. The heart was markedly hypertrophied, weighing 800 grams. The coronary arteries showed moderate atheroma.

an analysis of the deaths will clearly show how this can be lowered.

It must be borne in mind that the allocation of deaths was left entirely to the discretion of the investigator. An attempt was made to place each

TABLE 1. *Causes of Maternal Deaths.*

CAUSE	No. of DEATHS
Sepsis, including abortions	48
Medical (pneumonia, cardiac disease, chronic nephritis and so forth)	42

Hydatidiform mole	1
Psychosis	1
Sudden death	1
Anaphylaxis	1
Cancer of breast	1
Nonpuerperal	5
Total	247

case in which there was a possibility of more than one classification in the group that indicated the primary cause of death. This is illustrated by the following case:

Autopsy showed that the patient had rheumatic heart disease, pulmonary infarction and cerebral embolism. The patient died almost four weeks after delivery. The case was classed under "cardiac disease," because there was, in addition, a definite history of heart disease of many years' standing.

It is, in one sense, distinctly unfair to include cases of suicide in computing the maternal death rate. Pregnancy may have been a contributing factor in the mental unbalance associated with such fatalities, but the cases in no way represent obstetrical mismanagement. Furthermore, the case of aneurysm, although interesting in itself, was not a true maternal death.

Beginning with next week's issue of the *Journal*, the 48 cases of sepsis will be reviewed; and in subsequent issues, cases under the various other headings will be analyzed.

DEATH

HANDY—HARRY T. HANDY, M.D., of Scituate, died October 8. He was in his sixty-ninth year.

Born in Marion, Dr. Handy received his degree from Harvard Medical School in 1897. He was a fellow of the Massachusetts Medical Society and the American Medical Association.

He is survived by his widow, a brother and a sister.

MISCELLANY

NOTES

Eleven appointments to the teaching and research of the Harvard Medical School, effective during the present academic year, were recently announced as follows: assistant in ophthalmology, Fred S. Thorne, of Newton, M.D. Harvard '18; assistant in medicine, Jack D. O'Leary, of Brookline, M.D. Tufts '37; assistant in pediatrics, Edward L. Pratt, of Boston, M.D. Harvard '40; assistant in surgery, Arnold Starr, of Newton, M.D. Tufts '24; research fellow in anatomy, David L. Bassett, of Stanford University, California, M.D. Stanford '39; research fellow in medicine, Marshall Clinton, Jr., of Cambridge, Mass. Buffalo '40; research fellow in surgery, Mercier F. F. of Westmount, Quebec, Canada, F.R.C.S. (C) Royal Canadian College of Surgery '31; Austin Teaching Fellow in Physiology, Aristides A. P. Leao, of Rio de Janeiro, B.Sc. M.A. Harvard '42; instructor in surgery, David D. Bick, of Brookline, M.D. Tufts '23; assistant in bacteriology and immunology, Morris J. Pickett, of Boston, Ph.D. Stanford '42; research fellow in comparative pathology and tropical medicine, Henry D. Hoberman, of Bridgeport, Connecticut, Ph.D. Columbia '42. The appointments of Drs. Pickett and Hoberman are also effective in the Harvard School of Public Health.

CORRESPONDENCE

RELATION OF PERIPHERAL DISEASES TO PULMONARY FIBROSIS

To the Editor: In the past eighteen months, there have appeared in the *Journal* three papers of much greater significance than the implication of their titles. In the July 17, 1941, issue, Linenthal and Talkov reported 12 cases of pulmonary fibrosis in Raynaud's disease. In the September 17, 1942, issue, they reported two additional cases, whereas in the September 18, 1941, issue, Banks published a paper entitled, "Is there a Common Denominator in Scleroderma, Dermatomyositis, Disseminated Lupus Erythematosus, the Libman-Sacks Syndrome and Polymyositis Nodosa?" In the six cases reported by these three authors, Raynaud's disease, scleroderma and arthritis were associated with pulmonary fibrosis.

Ten years ago, I reported before the Boston Society of Psychiatry and Neurology a group of cases in which these conditions and Dupuytren's contracture were associated with pulmonary fibrosis and other pulmonary conditions. In the October, 1934, issue of the *Journal of Nervous and Mental Disease*, I reported twenty nine cases in which Raynaud's disease, scleroderma, Dupuytren's contracture, noninfectious arthritis and other peripheral conditions were associated with fibrosis and other pulmonary conditions, no prior description of this syndrome having been found in the literature.

Banks, Linenthal and Talkov, without having read my paper and, I believe, without obligation to any of the authors, have now reported six cases exhibiting the syndrome, including complete laboratory data and complete pathological data. I say "almost complete" because I believe that, when the clinical conditions in this syndrome appear clinically, the changes are present subclinically and may be found by the pathologist.

If this ten-year-old concept, that pulmonary fibrosis in Raynaud's disease, noninfectious arthritis, Dupuytren's

tion. At any rate, we cannot connect this finding with a dissecting aneurysm.

DR. WHITE: From my experience I should say the reverse, namely, that heart block, either auriculoventricular or intraventricular (bundle branch), is much more often evidence of chronic coronary heart disease than of an acute process. In most persons, heart block is discovered either accidentally by electrocardiograms or as a result of symptoms of faintness and not following a typical episode of acute myocardial infarction, whereas the great majority of patients who have perfectly classic attacks of acute myocardial infarction have no heart block at all or only for a few days, in the rare cases of posterior wall infarction. There are exceptions, but that is the rule.

DR. DIEUAIDE: Do you favor infarction rather than dissection here?

DR. WHITE: I should say that coronary heart disease, but not acute infarction, was one of the conditions present. The changes in the ST segments and T waves are more important than the presence of block with respect to an acute episode.

DR. DIEUAIDE: Concerning the rest of the electrocardiogram, the fact that the T waves were low in normal leads and not in Lead 4 gives us no help.

DR. WHITE: This record was taken about six hours after the attack.

DR. DIEUAIDE: In summary, my interpretation of the case is that the patient, who had hypertension, probably did have coronary sclerosis and that he suffered from chronic impairment of his myocardial reserve. I interpret the major accident to be a dissection of the thoracic aorta that extended down into the abdominal aorta.

DR. MALLORY: Would you like to speculate on the mechanism by which the dissection might have caused death.

DR. DIEUAIDE: You raise the question because of the long interval?

DR. MALLORY: Yes, in part. Dissection per se is not a lethal condition. Patients have had dissection sometimes with and sometimes without symptoms and have lived many years afterward.

DR. DIEUAIDE: I do not think I can offer a good explanation for it.

DR. WHITE: May I ask Dr. Dieuaide if he thinks a likely explanation of death might have been the final rupture of the adventitia of the aorta, with hemorrhage into one of the serous cavities?

DR. DIEUAIDE: Accepting the diagnosis, I should think that would be a natural end, but we have no data that describe what the termination was like.

DR. WHITE: It was sudden.

DR. MALLORY: The blood pressure strikes me as unusual—a very high diastolic pressure and an extremely low pulse pressure.

DR. WHITE: In both coronary occlusion and dissection of the aorta, I have seen high blood pressure maintained. I have noted hypertension in some cases only during coronary thrombosis, doubtless as the result of pain; thus the response of different individuals varies greatly. In this case, the maintenance of high blood pressure favors dissection of the aorta rather than myocardial infarct, as you have intimated.

CLINICAL DIAGNOSES

Hypertensive and coronary heart disease.
Dissecting aortic aneurysm
Angina pectoris.
Congestive failure.

DR. DIEUAIDE'S DIAGNOSES

Dissecting aneurysm of thoracic and abdominal aorta.
Hypertension
Coronary sclerosis.
Myocardial infarction, old

ANATOMICAL DIAGNOSES

Dissecting aneurysm of aorta and great vessels of neck
Cardiac tamponade.
Arteriosclerosis: coronary, moderate, and aortic, marked
Infarcts of kidneys, partial and complete.

PATHOLOGICAL DISCUSSION

DR. MALLORY: This man did have a dissection of the aorta. We found a tear in the intima about 2 cm above the aortic valve. From that point, dissection had occurred backward to the annularis of the aortic valve and forward almost down to the iliac arteries. One rather unusual feature of the case was that there was an extensive dissection of the carotid and innominate arteries. It is not uncommon for dissection to pass the bifurcation of the aorta and to extend several centimeters down the iliacs. There was little involvement of the iliacs here, whereas in contrast the dissection of the vessels of the neck was very marked. I think it is conceivable that, with a little closer observation, some symptoms might have been made out to indicate that, but there is nothing in the record.

The terminal episode was rupture of the outer layer of the aorta into the pericardium, with death from cardiac tamponade. The heart was markedly hypertrophied, weighing 800 grams. The coronary arteries showed moderate atheroma.

ies: No, because of the location. We never see fluid in that area. The heart re apparently normal.

MAN: The differential diagnosis here ut the types of mediastinal tumors. I discuss lesions arising outside the me-

chest to rest on the diaphragm, and it lodges posteriorly rather than anteriorly.

I do not believe this is an aneurysm, because no definite connection between the mass and the aorta was visualized. The presence of pulsations is not mentioned, although they are not absolutely neces-

FIGURE 1.

liastinum that eventually lodge in the mediastinum, and second, lesions arising in the mediastinum itself.

One should consider diaphragmatic hernia. Only a very unusual one lodges in the right chest. One might suppose that the hernia went through the anterior attachment of the diaphragm. This type, however, is extremely rare, and I mention it only in passing.

Intrathoracic goiter has to be considered, but it must be of an extremely unusual type to fit this case. Intrathoracic goiters in this region are rare; most occur in the upper mediastinum. Certainly the shape of this tumor is unusual for intrathoracic goiter. Usually, it is a single round nodule and not a lobulated mass that plunges down into the

sary for diagnosis. Moreover, there is no history or physical findings of syphilis, and the Hinton test was negative. I am not at all concerned about aneurysm.

In considering the diagnosis of mediastinal tumor, one must first settle the question whether the mass is benign or malignant. I think we can state definitely that this mass is not a malignant tumor. The patient was symptomless, except for inconstant pain; there was no evidence of invasion of surrounding structures and organs, and there was no toxemia. Consequently, we can rule out a malignant type of tumor.

Although I doubt that I can make a better diagnosis than just benign mediastinal tumor, I must consider the several varieties. The description of

the tumor, the short duration of pain and the unknown duration of the tumor are consistent with dermoid, which also is the commonest statistically. On the other hand, several cases with similar findings that have been discussed at these meetings were found to have had either a neurofibroma, chondroma, lipoma or cyst. We saw one mediastinal tumor here a year ago that gave similar symptoms and had a similar appearance in the x-ray films, which the pathologist called hemangioma. One should mention thymoma as a possibility. It must have extended from its origin in the thymus down to this region. I have no way of confirming this diagnosis.

As Dr. Holmes said, it is unusual to find encapsulated fluid in this location, although the history of pleurisy a month before admission raises the question of fluid in the pleural space. Moreover, lobulation of the mass argues strongly against encapsulated fluid. Consequently, I shall not consider it further.

In conclusion, I believe this is a benign mediastinal tumor, either neurofibroma or dermoid.

DR. WILLIAM B. BREED: I wonder if enough stress has been laid on the fact that this whole episode was ushered in by an acute respiratory infection. That may be of some importance, and the mass may still be encapsulated pus. Perhaps this point should be stressed just a little more than it was in the discussion.

DR. LERMAN: Dr. Churchill has emphasized many times that the symptoms of these patients have no relation to the mediastinal tumor. I have been influenced by his opinion. Many patients come in with bizarre complaints, and a tumor is found incidentally. I think the onset of the respiratory infection served to focus attention on something in the chest.

DR. RALPH ADAMS: Did this mass move with swallowing?

DR. TRACY B. MALLORY: I do not believe so.

DR. EDWARD D. CHURCHILL: This is all a guessing game, for it is very difficult to arrive at any preoperative diagnosis except mediastinal tumor, benign or malignant. There are two or three additional diagnoses that occurred to me as I listened to the discussion. I should think of a hernia through one of the apertures of the diaphragm and should have advised a barium enema. There is another lesion that we have come to recognize particularly along the right border of the pericardium,—namely, a thin-walled cyst containing clear fluid. These cysts are comparable to the cystic hygromas that are found in the neck. Perhaps Dr. Mallory can say whether they are of lymphatic origin or of endothelial origin from adjacent serous cavities.

I wish Dr. Holmes would take a stand on the question whether this particular patient should have received a diagnostic dosage of radiation therapy to rule out lymphoma or another radio-sensitive tumor before operation.

DR. HOLMES: As a general rule, I think the diagnosis should be established, whenever possible, before we subject a patient to x-ray therapy. But it depends largely on the severity of the operative procedure planned. If it is to be a simple operation, probably x-ray therapy should not be given; on the other hand, if it is a dangerous operation, I should advise giving a small dose.

DR. CHURCHILL: Will you feel badly if some day I enucleate such a tumor and it turns out to be lymphosarcoma or lymphoma?

DR. HOLMES: No.

DR. CHURCHILL: Will you, Dr. Mallory?

DR. MALLORY: No. It might be good treatment. I think when an isolated tumor is resectable it is wise to remove it, because very long cures often follow the procedure.

CLINICAL DIAGNOSIS

Mediastinal tumor (? dermoid cyst, ? neurofibroma, ? lymphoblastoma).

DR. LERMAN'S DIAGNOSIS

Benign mediastinal tumor (neurofibroma or dermoid).

ANATOMICAL DIAGNOSIS

Pleuropericardial cyst.

PATHOLOGICAL DISCUSSION

DR. MALLORY: This patient did turn out to have a cyst filled with perfectly clear fluid. The cyst has a fibrous wall with an occasional smooth muscle fiber in it, looking essentially like pleura. It is lined with a low cuboidal epithelium that occasionally seems multilayered, which is probably due to tangential sectioning; it seems likely that the epithelium lining was only a single layer thick. So far as the appearance of the cells is concerned, they could either be mesothelial, such as those that line the pleura, or endothelial, which one would find lining a lymphatic vessel. I do not believe I can answer Dr. Churchill's question. I have a little preference for the theory that this sac is made up of pleural or pericardial tissue than that it represents a cystic hemangiomatous tumor, such as a cystic neck.

DR. HOLMES: Perhaps it is a change in shape had a thin wall

DR. MALLORY: Should this tumor perhaps have been needled before operation?

DR. CHURCHILL: I do not think so.

DR. MALLORY: If it had been, could you have made the diagnosis?

DR. CHURCHILL: Probably, but we should not have known what to do in the way of treatment. I do not believe it is without danger to put a needle in so close to the pericardium. There is always a possibility that one is dealing with an aneurysm of the auricle.

Dermoids are likely to be a bit higher on the right and a little closer to the lung root. When a tumor lies in the cardiophrenic angle, a simple test must be seriously considered.

DR. MALLORY: Sometimes, there is a rather unusually large amount of fat tissue in that loca-

tion. Does that ever cause clinical confusion in a case of this sort?

DR. CHURCHILL: I do not recall having been misled by a fat pad.

DR. ALLEN G. BRAILEY: The patient would have been perfectly well if left alone?

DR. CHURCHILL: I think she would have.

DR. MALLORY: We have no idea of the rate with which these cysts grow. It is quite doubtful that this had anything to do with the symptoms.

DR. CHURCHILL: I also think that it is very doubtful. One must remember, however, that the presence of an x-ray shadow of this type is sufficient reason for employment rejection by many large industrial plants and, of course, by the armed forces. She can now join the WAACs or WAVES.

COMMUNICATIONS should be addressed to the *New England Journal of Medicine*, 8 Fenway, Boston, Massachusetts.

AN ELOQUENT SERMON

The number of physicians on extended active duty and the figures on the 1942 quotas, as of September 1, are now available from the Procurement and Assignment Service. The latter furnish interesting and disturbing data, particularly concerning some of the New England states. The state providing the lowest percentage of its quota of physicians for 1942 is Nevada, which has obtained but 56 per cent. The second lowest is Illinois, in which the figure is 63 per cent. The next two lowest are Connecticut and New York, each having supplied but 64 per cent of their quotas. For Massachusetts, the figure is 67 per cent; for New Hampshire, 79 per cent;

for Vermont, 82 per cent; for Rhode Island, 84 per cent; and for Maine, 99 per cent.

For a community spoken of as the "Cradle of Liberty," Massachusetts hardly shows to advantage in this picture when compared with such states as New Mexico with 205 per cent of its total quota, Louisiana, with 196 per cent, Alabama, with 179 per cent, South Carolina, with 160 per cent, Kentucky, with 159 per cent, and North Carolina, with 151 per cent. Twenty-six states in the Union have supplied above 100 per cent of their quotas. When one realizes that Massachusetts stands fifth from the bottom, only four other states, Nevada, Illinois, Connecticut and New York, having lower percentages, then it can be said that these figures preach an eloquent sermon.

A SEMICENTENNIAL

It is occasionally valuable to stop in the course of one's daily rounds and survey the activities of one's fellow workers. The opportunity usually arises in relation to an anniversary, a birthday or the completion of a long period of service. Such an event will be celebrated on Friday, October 23, at the Boston Medical Library, for on that date Mr. James F. Ballard, the director, will have completed a service of fifty years as a valued employee of that institution.

Beginning in 1892, as a boy helping in the stacks, Mr. Ballard has worked his way up to the directorship of the library and has made a name for himself in the front rank of medical librarians. This position has been recognized by his election to the presidency of the Medical Library Association and to other offices. He is widely known for his classification of medical books, which is used in almost every medical library in this country. In the past, he has been consulted by the Rockefeller Foundation and its General Education Board for advice in establishing medical libraries in this country and abroad. There are few men living who know more about medical books and their accession, classification and care. His knowledge of medical periodicals, moreover, is extensive.

It should be pointed out that, in addition to his work as a medical librarian, he has been for many years a substantial citizen of the Town of Milton, has sent three of his children through college and has two sons now serving in the armed forces.

This creditable career is largely the result of his own efforts, for his preliminary schooling was scant and knowledge came to him largely through continued application and long hours of hard work. His nights, Sundays and holidays, which for many people are times of relaxation, have been freely and almost continuously given to the Boston Medical Library. Rarely would one not find him at work in the evening or on Sunday afternoon, particularly during the last twenty five years, when he has had executive responsibility.

It is of interest, moreover, that he chose as his hobby one of the most difficult branches of medical literature, namely, incunabula or books printed in the fifteenth century. Here he had to acquire a working knowledge of Latin and a deep appreciation of these books and their significance, as well as a considerable technical knowledge regarding their classification, for the printer, place of publication and author are often unknown. There are, in addition, many details to be learned about the type used, the paper, the dating of the publication and the relation of the printed book to the same material in manuscript form circulated before the discovery of printing. All these have been Mr. Ballard's particular interest in the last two decades, and the library has turned to him for a new catalogue of its renaissance and medieval manuscripts and its incunabula, which is now in the course of publication.

Few individuals have the opportunity of serving one organization for half a century. It is even rarer to have the service so genuine and efficient as that given by Mr. Ballard to the Boston Medical Library. The *Journal* therefore takes great pleasure in extending to him heartiest congratulations on this semicentennial anniversary and wishes him good health in the future so that he may continue his work, the thing nearest his heart.

MEDICAL EPONYM

ROVSING'S SIGN

Dr Thorkild Rovsing (1862-1927), director of the Surgical Clinic at the University in Copenhagen, described "Indirektes Hervorrufen des typischen Schmerzes an McBurney's Punkt [Indirect Elicitation of Typical Pain over McBurney's Point]," in the *Zentralblatt für Chirurgie* (34²: 1257-1259, 1907). Being unable satisfactorily to examine in the usual way two patients whom he suspected of having appendicitis, he was able to bring out the typical pain by this maneuver. A portion of the translation follows:

Both patients showed such unusual sensitiveness to palpation that a careful examination of the region of McBurney's point seemed not only impossible but inadvisable. It occurred to me that the typical pain might possibly be elicited by pressure on the descending colon, in the *left iliac fossa*. I laid my left hand flat on the abdomen and with the right hand forced its fingers down against the colon, compressing it. The hand was then allowed to glide upward toward the sigmoid flexure.

R. W. B.

MASSACHUSETTS MEDICAL SOCIETY

ANALYSIS OF CAUSES OF MATERNAL DEATH IN MASSACHUSETTS DURING 1941

The five year study of the maternal mortality in Massachusetts, conducted by the Section of Obstetrics and Gynecology, ended with the deaths occurring during the year 1941. Two hundred and forty seven deaths were listed by the Massachusetts Department of Public Health for investigation, and of these, 5 were found, after investigation, to have no relation to pregnancy. Although these are included in the tabulation of the causes of maternal deaths (Table 1), the cases will not be reviewed. An example of such a case is as follows:

Following the death of this patient, autopsy proved that pregnancy did not exist. The patient died of septicemia, peritonitis and parametrial abscess. One pregnancy preceded this fatality by eleven months, but there was no subsequent history of abortion, nor did the autopsy reveal any uterine change characteristic of pregnancy.

The death rate, 29 per 1000 living births, was practically identical with that for 1940, which was 28 per cent. Although that is a creditable figure,

an analysis of the deaths will clearly show how this can be lowered.

It must be borne in mind that the allocation of deaths was left entirely to the discretion of the investigator. An attempt was made to place each

TABLE 1. *Causes of Maternal Deaths.*

CAUSE	NO OF DEATHS
Sepsis, including abortions	48
Medical (pneumonia, cardiac disease, chronic nephritis and so forth)	42
Embolism	39
Hemorrhage, including separated placenta and placenta previa	31
Albuminuria and eclampsia, including toxemia	27
Surgical	10
Anesthesia	10
Ectopic pregnancy	6
Ruptured uterus	5
Transfusion	4
Suicide	2
Inverted uterus	2
Cerebral hemorrhage	2
Pernicious vomiting	2
Cause unknown	2
Shock	2
Abdominal pregnancy	1
Aneurysm	1
Chemical	1
Hydatidiform mole	1
Psychosis	1
Sudden death	1
Anaphylaxis	1
Cancer of breast	1
Nonpuerperal	5
Total	247

case in which there was a possibility of more than one classification in the group that indicated the primary cause of death. This is illustrated by the following case:

Autopsy showed that the patient had rheumatic heart disease, pulmonary infarction and cerebral embolism. The patient died almost four weeks after delivery. The case was classed under "cardiac disease," because there was, in addition, a definite history of heart disease of many years' standing.

It is, in one sense, distinctly unfair to include cases of suicide in computing the maternal death rate. Pregnancy may have been a contributing factor in the mental unbalance associated with such fatalities, but the cases in no way represent obstetrical mismanagement. Furthermore, the case of aneurysm, although interesting in itself, was not a true maternal death.

Beginning with next week's issue of the *Journal*, the 48 cases of sepsis will be reviewed; and in subsequent issues, cases under the various other headings will be analyzed.

DEATH

HANDY—HARRY T. HANDY, M.D., of Scituate, died October 8. He was in his sixty-ninth year.

Born in Marion, Dr. Handy received his degree from Harvard Medical School in 1897. He was a fellow of the Massachusetts Medical Society and the American Medical Association.

He is survived by his widow, a brother and a sister.

MISCELLANY

NOTES

Eleven appointments to the teaching and research staff at the Harvard Medical School, effective during the present academic year, were recently announced as follows: assistant in ophthalmology, Fred S. Thorne, of Newtonville, M.D. Harvard '18; assistant in medicine, Jack D. Cohen, of Brookline, M.D. Tufts '37; assistant in pediatrics, Edward L. Pratt, of Boston, M.D. Harvard '40; assistant in surgery, Arnold Starr, of Newton, M.D. Tufts '28; research fellow in anatomy, David L. Bassett, of Stanford University, California, M.D. Stanford '39; research fellow in medicine, Marshall Clinton, Jr., of Cambridge, M.D. Buffalo '40; research fellow in surgery, Mercier Fauteux, of Westmount, Quebec, Canada, F.R.C.S. (C) Royal Canadian College of Surgery '31; Austin Teaching Fellow in Physiology, Aristides A. P. Leao, of Rio de Janeiro, Brazil, M.A. Harvard '42; instructor in surgery, David D. Berlin, of Brookline, M.D. Tufts '23; assistant in bacteriology and immunology, Morris J. Pickett, of Boston, Ph.D. Stanford '42; research fellow in comparative pathology and tropical medicine, Henry D. Hoberman, of Bridgeport, Connecticut, Ph.D. Columbia '42. The appointments of Drs. Pickett and Hoberman are also effective in the Harvard School of Public Health.

CORRESPONDENCE

RELATION OF PERIPHERAL DISEASES TO PULMONARY FIBROSIS

To the Editor: In the past eighteen months, there have appeared in the *Journal* three papers of much greater significance than the implication of their titles. In the April 17, 1941, issue, Linenthal and Talkov reported three cases of pulmonary fibrosis in Raynaud's disease, and in the September 17, 1942, issue, they reported two additional cases, whereas in the September 18, 1941, issue, Banks had a paper entitled, "Is there a Common Denominator in Scleroderma, Dermatomyositis, Disseminated Lupus Erythematosus, the Libman-Sacks Syndrome and Polyarteritis Nodosa?" In the six cases reported by these three authors, Raynaud's disease, scleroderma and arthritic conditions were associated with pulmonary fibrosis.

Ten years ago, I reported before the Boston Society of Psychiatry and Neurology a group of cases in which these conditions and Dupuytren's contracture were associated with pulmonary fibrosis and other pulmonary conditions, and in the October, 1934, issue of the *Journal of Nervous and Mental Disease*, I reported twenty-nine cases in which Raynaud's disease, scleroderma, Dupuytren's contracture, noninfectious arthritis and other peripheral conditions were associated with fibrosis and other pulmonary conditions, no prior description of this syndrome having been found in the literature.

Banks, Linenthal and Talkov, without having read this paper and, I believe, without obligation to any other authors, have now reported six cases exhibiting this syndrome, including complete laboratory data and almost complete pathological data. I say "almost complete pathological data" because I believe that, when one of the conditions in this syndrome appears clinically, the others are present subclinically and may be found by the pathologist.

If this ten-year-old concept, that pulmonary fibrosis, Raynaud's disease, noninfectious arthritis, Dupuytren's

contracture, sclerodema and some other conditions are not clinical entities but parts of a syndrome, is once accepted, then progress in the study of every one of these conditions should be accelerated

BOOK REVIEWS

The 1941 Year Book of Industrial and Orthopedic Surgery Edited by Charles F Painter, MD 12°, cloth, 432 pp, with 353 illustrations Chicago The Year Book Publishers, Incorporated, 1941 \$3.00

Dr Painter is to be congratulated on the clear and concise manner in which he has summarized the contributions to orthopedic surgery that have been published during the past year. Each article has a new idea and a different approach to treatment. A larger section has been written on industrial medicine in an attempt to keep pace with this important branch of medical practice. There are numerous excellent illustrations. The selection and arrangement of the material are good. Although no two persons compiling a year book on orthopedic surgery would make identical selections of articles, there are few who would criticize the selections Dr Painter has made. This little book should be on the reading list of all industrial and orthopedic surgeons.

Rabies By Leslie T Webster, MD. 8°, cloth, 168 pp, with 8 illustrations and 22 tables. New York: The Macmillan Company, 1942 \$1.75.

In much of the literature on rabies, the lines between scientific fact and speculation have not been clearly drawn, and many of the articles are not easily accessible. This book is a compilation of existing literature and attempts to furnish sound data to those who would otherwise have difficulty in obtaining it. The first part of the book discusses the diagnosis of the disease, and the second covers its prevention, citing controversial results. It is stated, contrary to popular opinion, that "there is no definite evidence that vaccine treatment, following exposure to rabies, confers any striking protection against the disease and that investigations of the efficacy of vaccine treatment should be continued from all angles." The author states emphatically, however, that persons exposed to rabies should be given vaccine treatment with confidence that then there is small likelihood of development of the disease.

This book should be of great value to physicians, veterinarians, public health officials and research workers but, because of its technical nature, is not suitable for laymen.

The 1941 Year Book of Pathology and Immunology Edited by Howard T Karsner, MD *Immunology* Edited by Sanford B Hooker, MD 12°, cloth, 623 pp, with 136 illustrations Chicago The Year Book Publishers, 1941 \$3.00

This book gives well selected reviews of the developments in pathology and immunology during 1941. However, comparing the abstracted articles with such a complete list as that given in the *Index Medicus*, one finds that it deals almost entirely with papers in English,

owing to abnormal wartime conditions, which limit the availability of almost all scientific journals issued abroad.

The twelve chapters on pathology, edited by the experienced and dynamic director of the Institute of Pathology of Western Reserve University, take up 349 pages and review general pathology and the pathology of tumors, of the cardiovascular, hematopoietic, respiratory, urinary and nervous systems, of the alimentary tract, of the male and female genitalia, of the organs of locomotion and of the glands of internal secretion. In this section, there are 129 illustrations, all reproduced from the articles abstracted, most of them are photographs showing histologic features of lesions, which are of great value to the reader. Among the large amount of information yielded by hundreds of analyses that are presented to the reader, the following are of particular interest: a review prepared at the invitation of the editor by Virgil A Moon on the pathologic changes underlying the development of shock, a summary given by Eben J Carey of his contributions to knowledge of the function of striated muscles, an abstract of studies on the bicuspidal semilunar valves, furnished by Simon Koletsky, an interesting review prepared by Aldo Lunsada on favism, and data from Page on the new aspects of the nature of chemical changes occurring in arteriosclerosis. The interpretation of the analyses is helped by timely observations from the editor. A few papers, such as the one of Esmond R Long entitled "Constitution and Related Factors in Resistance to Tuberculosis" and three others, dealing respectively with transmission of susceptibility to cancer, the identity of inhibitor and antibody" in virus induced rabbit papillomas and the union in vitro of the papilloma virus and its antibody, are included in the section covering the pathology of tumors although their subjects, being of immunologic nature, ought to be included in the section on immunity to tumors.

The second part starts with a tribute to Hans Zinsser by his successor, J Howard Mueller. Zinsser, who served Harvard, Columbia and Stanford universities as bacteriologist and immunologist for more than thirty five years, had been properly regarded, for more than a quarter of a century throughout the world, as the academic personification of immunology applied to the study of infectious diseases. The chief attraction in this part of the book is found in the chapter on blood groups, where the recent advances in blood transfusion, inaugurated by Landsteiner and Wiener's discovery of the Rh factor and its relation to erythroblastosis foetalis, are authoritatively discussed by Wiener himself and by Philip Levine. The contributions in the various fields of immunity are divided into chapters dealing with immunity to bacterial diseases, immunity to viral diseases, immunity to diseases due to protozoa, fungi and higher parasites, immunity to tumors, chemotherapy, anaphylaxis and allergy, blood groups, immunochemistry, bacteriology and bacterial nutrition, and technics and miscellaneous topics. In the first chapter, the influence of war is reflected in the prevalence of papers dealing with tetanus, although the flow of publications on immunity concerning diphtheria and pneumococcal infections and so forth is not lowered. In the chapter on viral infections, in which an introductory article by Thomas M Rivers gives a résumé of current developments in this field and the growing importance of vaccines for prevention, the recent research work on bacteriophage, encephalomyelitis, choriomeningitis, poliomyelitis and so forth is ably reviewed, however, owing to the war and to the interest in Horsfall's vaccine, papers dealing with influenza virus prevail. The chapter on the immunology of para-

sitic diseases supplies additional information to that included in Culbertson's book on immunity against animal parasites. Immunity to tumors supplements the section on their pathology edited by Karsner, where is the chapter on chemotherapy merely supplements the subject, which is more extensively reviewed in other volumes of the series, its inclusion being justified by a sort of synergism between chemotherapeutic agents and antibodies in pneumonia and by the remarkable contributions supplied to this field of gramicidin and tyrothricin, the bactericidal fractions prepared from René J. Dubos's aerobic, sporulating soil bacillus. Those especially interested in the fields of anaphylaxis, allergy and immunochemistry in the realm of antigens and antibodies will find these sections particularly instructive on account of the critical remarks and suggestions, which are presented as a comment of the editor to some of the papers reviewed. A few illustrations and a table showing the clinically important cutaneous tests, which have been taken from an article of Charles A. Janeway, also give useful information and witness the ability of the editor to convey knowledge to the reader. When details on the methods used are essential, as in Landsteiner's and Di Somma's sensitization of animals with simple chemical compounds or in Heidelberger's quantitative chemical studies on complement, the editor reproduces them thoroughly from the original articles. An up-to-date report on the developing egg as a culture medium heads the reviews on bacterial nutrition, and a description of the electron microscope begins the last chapter, which is devoted to techniques and miscellaneous topics.

A comprehensive index to subjects and authors, covering both pathology and immunology, supplies a valuable guide to this book.

Biological Symposia. A series of volumes devoted to current symposia in the field of biology. Edited by Jaques Cattell. Vol. V. *Comparative biochemistry: intermediate metabolism of fats, carbohydrate metabolism, biochemistry of choline.* Edited by Howard B. Lewis, Ph.D. 8°, cloth, 247 pp., with 31 tables, 20 figures and 2 plates. Lancaster, Pennsylvania: The Jaques Cattell Press, 1941. \$3.00.

This is the latest of a series in biology published by the Jaques Cattell Press, and comprises the four symposiums arranged by the Council of the American Society of Biological Chemists for the April, 1941, meeting of the Federation of American Societies for Experimental Biology. It is thus well planned and authoritative. The contributors include such eminent investigators as Samuel Soskin, H. E. Longenecker, C. F. Cori, Otto Meyerhof and Vincent du Vigneaud. There are fifteen papers in all. Each is limited to ten to fifteen pages, which makes assimilation of the subject matter easy.

The first symposium, on comparative biochemistry, seeks to show some of the phases of modern biochemistry as they apply to plants and to animals and birds. An interesting question raised in plant biochemistry is the significance of the alkaloids, which may represent unextractable end products of the plant's nitrogen metabolism. The importance of niacin (nicotinic acid), choline and the betaines in plants, as well as in man, is discussed. In a paper on end products of nitrogen metabolism in animals, a comparative study is made of mechanisms of conjugation of nitrogenous products, and of variations in uric acid and purine metabolism. A third paper, on the merging of growth factors and vitamins, points out that choline is an essential growth factor for the pneumococcus, and nicotinic acid for *Staphylococcus aureus*.

In the symposium on the intermediate metabolism of fats, Soskin and Levine state that ketone bodies are formed because of faulty carbohydrate oxidation, but occur normally and independently of such oxidation. The peripheral tissues of the diabetic patient dispose of ketone bodies as fast as those of the normal person, and when ketone bodies appear in excess, it is due only to accelerated production of these substances in the liver. Thus the "ketogenic/antiketogenic ratios," as formerly used, are meaningless.

One of the most interesting papers in the book is that of Longenecker on the formation of animal body fat. It has recently been shown, by "tagging" molecules with deuterium in place of hydrogen atoms, that the depot fat, instead of being laid down only in periods of excess food intake, is constantly in a state of flux, although its amount may not change. The conversion of fat to carbohydrate has also been traced by the use of deuterium. It was shown experimentally by Longenecker that protein can be converted to fat in the animal body. In these conversions between carbohydrate, protein and fat, certain members of the vitamin B complex are essential.

The symposium on carbohydrate metabolism comprises four papers, all dealing with enzyme reactions, the oxidation catalysts, including the flavoproteins and cytochromes, the process of aerobic phosphorylation of glycogen, by which the energy from oxidations is made available to the cell for its use; the "oxidoreductions," or anaerobic molecular rearrangements; and the oxidation of pyruvic acid by the "citric acid cycle," essential in intermediate carbohydrate metabolism.

The fourth symposium, on the biochemistry of choline, is of great interest. Choline has recently been shown to prevent or cure fatty livers in depancreatized dogs or in rats fed a high-fat diet. This property of choline is known as its "lipotropic effect." Choline deficiency in the diet causes an acute hemorrhagic degeneration in the kidneys of rats. In the body, choline stimulates the formation of phospholipids, permits the productions of acetylcholine and, most significant, supplies "labile" methyl groups that the body cannot synthesize but must have for numerous methylations. One paper discusses the enzyme, cholinesterase, which destroys acetylcholine. In the final paper, du Vigneaud discusses the interrelations between choline and other methylated compounds. He and his co-workers, by the use of deuterium in methyl groups, were able to show that choline is definitely an essential dietary factor and that its methyl groups are concerned with methionine and sulfur metabolism, with creatine metabolism and with fat metabolism.

Altogether, this most stimulating collection of papers is highly recommended.

Psychosurgery: Intelligence, emotion and social behavior following prefrontal lobotomy for mental disorders. By Walter Freeman, M.D., Ph.D., and James W. Watts, M.D. With special psychometric and personality profile studies by Thelma Hunt, M.D., Ph.D. 4°, cloth, 337 pp., with 81 illustrations. Springfield, Illinois: Charles C. Thomas, 1942. \$4.00.

Since 1900, there have been three important new approaches toward solving the problem of mental disease. The first is psychoanalysis, which has brought many new ideas to medicine, especially regarding emotional patterns. The second is shock therapy, employing insulin, Metrazol and other chemical and physical means of altering or influencing the course of mental disease. The third

and newest of these methods involves operation on the brain itself—prefrontal lobotomy

This new book, the first of its kind, describes the intelligence, emotions and social behavior of patients who have undergone prefrontal lobotomy for mental disorders. The work has been carefully planned and executed and leaves little to be desired in terms of complete and conscientious reporting. The surgeon will find the book interesting, just as he might have found Dr. Cushing's book on meningiomas of interest. In fact, the general outline of case study employed by Cushing has been followed by the authors. The psychiatrist will find the reports valuable in view of the alterations in personality following operation.

This is an unusual book in that it combines three important kinds of observation in one document. It includes the clinical history, with emphasis on the mental disorder, and gives a detailed account of the surgical procedure that was followed and of the follow up reports, which are interesting and unique. In some cases, neuropathologic reports were available, and in the more successful cases detailed psychometric studies were utilized to measure the changes and improvement shown by the patient.

The authors have been very modest in reporting their results. They are keenly aware of the limitations and the experimental aspects of their studies. At the same time, they report enough substantial data to support interesting and encouraging conclusions. Until now, physicians have had to ask, Does cutting into the brain improve insanity? The answer contained in this book is, In some cases, improvement from certain psychiatric disorders has followed prefrontal lobotomy. The book is quite technical, but each physician should read it for himself to obtain his own impression. There are a few minor defects, which can be discounted in view of the great historical importance of the book.

Many neurosurgeons at present are extremely conservative in their approach to mental disorder. This book clearly indicates the type of patient for whom the operation may be suitable, and it describes with adequate clarity the technique and general management of the case.

In some quarters, the entire process of operating on the brain for mental disorder has been frowned on, since it has been regarded as too dangerous and too radical. From a study of the cases in this book, however, one gains the impression that the actual operation is not so radical as it sounds.

The book will probably do much to focus the attention of neurosurgeons and general surgeons on this problem and to stimulate their interest in the subject and their criticism of the method.

From Cretin to Genius By Serge Voronoff 8°, cloth, 281 pp. New York: Alliance Book Corporation, 1941 \$2.75

The author analyzes, in a philosophical vein, genius, the soul, the mind, the creative process and similar topics. He uses a wealth of observations on poets, writers, composers, artists and scientists, with considerable historical accuracy. When he comes to theorize about his material, however, he falls far short of scientific standards. He concludes, for example, that the conscious ego occupies the superficial layer of the brain, and the subconscious the lower layers. It is from these lower layers that come the profoundest thoughts of philosophers, the loftiest flights of poets, the proudest creations of artists, the noblest discoveries and inventions of scientists. Again, when discussing the electroencephalogram, he writes: Scanning the chart, we can tell whether the thought was joyous or sad, whether

the feeling experienced was happy or painful. For the electric waves change according to the character of each thought and each feeling." These are far cries from the known physiologic facts, and based on such premises, the author's arguments are highly speculative and often unwarranted.

Preeclamptic and Eclamptic Toxemia of Pregnancy By Lewis Dexter, M.D., and the late Soma Weiss, M.D. In collaboration with Florence W. Haynes, Herbert S. Sise and James V. Warren 8°, cloth, 415 pp., with 47 illustrations. Boston: Little, Brown and Company, 1941 \$5.00

This monograph approaches the subject from the standpoint of the internist and the research worker, rather than from that of the obstetrician. The obstetric point of view, however, is not lost sight of, since the practical application of the research carried out is stressed throughout the book. The purpose of the monograph, as stated by the authors, is twofold: to describe their experiences and interpret their findings, and to analyze the literature in the light of their studies. A timely, well-sifted bibliography is appended at the end of each chapter, making important references readily available.

Consideration is given to the nature and significance of generalized edema in normal pregnancy and in toxemia of pregnancy. The authors believe that the etiology of generalized edema cannot be explained by the well recognized mechanical causes of edema formation, including hydrostatic pressure in the capillaries, increased capillary permeability to protein and hypoproteinemia. Nor do they regard it as due to cardiac failure, anemia, vitamin B₁ deficiency, myxedema or excessive ingestion of sodium salts. By exclusion, they suspect a primary, humoral etiology. The relation of the pressor fraction of the posterior pituitary gland to the hypertension of toxemia of pregnancy is fully discussed. Under the conditions of their experiments, Pitressin did not produce permanent hypertension when administered in both large and small repeated doses. No significant histologic changes were observed in the animals under the experimental conditions employed. So far as could be determined by the methods of extraction now in use, the pressor substance, renin, is not concentrated in the placentas of women with hypertension during pregnancy. A chapter is devoted to the arterial blood pressures of newborn babies of normal and hypertensive mothers, no significant difference in the blood pressures was found to exist. Hormones have not induced a syndrome strictly comparable to human toxemia in animals, nor does toxemia occur in them spontaneously. From their studies, the writers postulate that the improvement in blood pressure, albuminuria and edema that occurs promptly in toxemic patients following delivery is due to the removal of the placenta rather than to the removal of the fetus or to the relief of pressure on neighboring structures by the enlarged uterus.

One hundred and fifty-nine pages are devoted to the pre-eclamptic and eclamptic toxemias of pregnancy (arterial hypertension in pregnancy and the hypertensive toxemia of pregnancy). Eighty cases showing hypertension previous to the pregnancy studies were exhaustively investigated. The illustrations of the pathologic processes studied are clear and well chosen. An interesting diagram representing the factors involved in toxemia and post toxemia is presented. Two types of hypertension in pregnancy have been differentiated—the pre-pregnant hypertension, uninfused by pregnancy, and hypertensive toxemia of preg-

nancy, which may occur in patients with or without pre-pregnant hypertension.

The chapter on treatment starts with the earlier methods, and considers all advances made in the management of this disorder. The authors advise a middle course, stressing individualization of the patient. Methods that have been found valuable are summarized under "Present-Day Treatment." Diekmann's and Irving's treatments are completely outlined and cover what is accepted as satisfactory management. Prenatal care is emphasized as an essential part of the care of these patients.

The text is interesting to read, and the illustrations are excellent. This monograph will benefit not only the student of the toxemias of pregnancy and the research worker but also the general practitioner and the clinical obstetrician.

Immunology. By Noble P. Sherwood, Ph.D., M.D. Second edition. 8°, cloth, 639 pp., with 27 illustrations and 7 color plates. St. Louis: The C. V. Mosby Company, 1941. \$6.50.

This is the second edition of an introductory textbook intended for the use of medical students and others interested in immunology and serology. It contains much that should interest the clinician.

It is clearly and simply written. The author is careful to define terms that may be unfamiliar to some of his readers. The material has been rearranged so that it may be outlined more readily, and two new chapters, one on the reticuloendothelial system and the other on serum reactions, have been added. A brief introduction to colloid chemistry has been retained. Most of the references, which are unusually numerous and well chosen, have been brought up to date. The index is adequate, typographical and grammatical errors are few, and the diagrams and illustrations, several in color, are helpful.

The author tends to cite in detail the conclusions of individual research workers, which sometimes leads to unnecessary duplication. At the ends of many chapters, however, he presents well-integrated summaries and his own interpretations of the often conflicting experimental data. The historical aspects of the various subjects are briefly but adequately covered. The chapters on antigens, antibodies and specificity as applied to the laboratory diagnosis of the common infectious diseases, although a little more up to date than they were in the first edition, are not so authoritatively covered as they are in certain other texts. The chapters on complement fixation and other serologic technics, however, are especially well done.

Directory of Medical Specialists Certified by American Boards, 1942. 8°, cloth, 2495 pp. New York: published for the Advisory Board for Medical Specialists by Columbia University Press, 1942. \$7.00.

This second edition of the *Directory of Medical Specialists* contains over 18,000 names of doctors certified by the fifteen American boards. Since the publication of the first edition in 1939, over four thousand physicians have successfully taken board examinations, and their names are to be found in the new edition. New information, especially concerning the graduate and postgraduate education of the diplomates, has been added. The directory has been increased in size by over nine hundred pages. Three new boards, on anesthesiology, plastic surgery and neurologic surgery, have been established since 1939, and their membership is included in the directory.

The indexing is seriously defective, since it omits the page on which the entry to the individual person is made.

This omission causes unnecessary delay when one desires information on a particular person. One must first look for the name in the index, where the address and certifying board are found. This is a poor beginning, for it is necessary to look in succession for the special board, the state and the city or town, which are arranged alphabetically. All this searching would be obviated if the index noted the page in the volume where the name is listed. It is hoped that the editors will make this change in the next edition.

The work is extremely bulky, but is of inestimable value as a book of reference.

Diseases of the Nervous System, Described for Practitioners and Students. By F. M. R. Walshe, O.B.E., M.D., D.Sc., F.R.C.P. (Lond.), D.Sc. (hon.). Second edition. 8°, cloth, 35 pp., with 32 illustrations. Baltimore: The Williams and Wilkins Company, 1941. \$4.50.

The fact that a second edition of this book was called for within two years is a tribute to its worth. The volume is a kind of personal report from a distinguished British neurologist, giving a summary of his experiences in a difficult field of medicine. Because of the outstanding position held by the author and his ability to write clearly and comprehensively, the book may safely be put in the hands of medical students and practitioners.

Readers should be warned, however, that they may find some personal reactions, especially to treatment, not widely held in this country. Such a statement as "trypanamide is used in the post-pyrexial treatment of dementia paralytica" is correct but the drug is used extensively and favorable in other ways. Also, the statement that "the so-called Bulgarian belladonna treatment has no advantages over other measures" in the treatment of post-encephalitis Parkinsonism is too dogmatic for a controversial issue. Some drugs are referred to by their British trade names, unfamiliar to many American physicians. The Bragg-Paul type respirator is recommended, but in this country the Drinker box type is almost routinely used. With these points in mind, however, an American reader will find little difficulty in gaining a knowledge of clinical neurology from this book, which reflects the sound views of a leader in the field.

Your Teeth: Their past, present and probable future. By Peter J. Brekhuis, D.D.S. With a foreword by Irvine McQuarrie, Ph.D., M.D. 8°, cloth, 255 pp., with 20 illustrations, 31 plates and 7 tables. Minneapolis: The University of Minnesota Press, 1941. \$2.50.

This volume represents a compilation of facts and theories pertaining to dental health. The book is not intended as a text for the dental practitioner or student, but fills a gap as an informative source, useful to the layman as well as to the dentist.

Excellent chapters on the biologic and anthropologic factors concerning the development and loss of teeth are presented. A discussion on the causes of caries and pyorrhea, with a voluminous bibliography, is especially valuable.

A program for prevention of caries, with special reference to the care of children's teeth, is constructive and worthy of consideration in mapping out a nationwide program for the control of dental caries, which is so widespread in present civilization.

The author has approached the subject from a long experience in both clinical and scientific studies, with a broad vision of the future of dentistry and suggestions for further investigative studies.

NUMBER 17

AUDIOMETRY IN GENERAL PRACTICE

WERNER MUELLER, MD*

BOSTON

"THE proof of the deafness is in the hearing," to paraphrase an old adage. Essential as the physical examination of the ear is, it gives no accurate clue to the efficiency of that ear. One is often amazed at the acuity of an ear showing the effects of severe mechanical damage, where a person presenting anatomically perfect eardrums may be profoundly deaf. If one adds to this the fact that in by far the greatest number of cases the onset of the deafness is very insidious, one may say that audiometry is of paramount value in the detection of deafness. It is the purpose of this paper to describe some of the various means and methods of testing hearing, especially those that should be incorporated in the daily routine of medical practice.

For the past several years, two types of electric audiometer have been extensively used by otologists, hospitals, laboratories and schools in the detection and the measurement of deafness. The so-called "pure tone" audiometers produce musical tones of variable pitch and intensity by means of electric oscillators. With their aid, the hearing acuity of an ear can be charted in the form of a curve. Their use requires a good deal of practice and application, especially since, in spite of their much vaunted "scientific accuracy," they do not account for the intangibilities of the human element. Audiometry, it must be remembered, is largely a subjective test unless one resorts to the "conditioned reflex" methods of the animal experimenter. As a matter of fact, in the following paper, Dr. Guilder states that she has successfully used that method in her work on preschool children. Far more applicable in crusade work against deafness are the so-called "group audiometers," which have been used for some years in the public schools of Massachusetts and other states. The group audiometer consists of a phonograph with an electric pick up to which as many as forty earphones can be connected. The disks

used in the phonograph are carefully made recordings of monosyllables or numbers, which the pupils must write down as they hear them. Any pupil whose record sheet shows more than the permissible number of mistakes is then given a note to the parents advising them of the fact that the child has a hearing defect, and that they should consult their family physician, who refers the patient to an otologist or an ear clinic, where more accurate tests can be made. Rough as the group audiometer test, also called "screen test," may be, it is surprising how frequently even very slight losses of hearing are being detected. It can safely be said that in the majority of such cases the hearing loss is entirely unsuspected by parents and teachers alike, to say nothing of the patient. It stands to reason that such a program of deafness detection is of the greatest service to the public, and it is to be hoped that ultimately all the states of the Union will avail themselves of the systematic use of the group audiometer in the public and other schools.

The electric audiometers just described are obviously not adapted for the purpose of the busy general practitioner, who must have more easily available means for testing a patient's hearing. Undoubtedly, the oldest and, for all practical purposes, the most valuable of these is the human voice. The voice test has of late (since the introduction of the electric audiometer) been much maligned as being "unscientific and inaccurate." It must not be forgotten, however, that the human voice is more important to the human ear than any other sound. In general practice, it is much more essential to determine quickly and roughly the hearing acuity for the voice than to measure it "accurately" in terms of cycles and decibels. Two types of voice are usually and properly employed: the whispered and the conversational.

Of the two, the whisper is the more reliable because, as a rule, it is easier to keep it on a fairly even intensity level. A few simple rules should be observed. A "stage whisper" is not permissible.

*Assistant surgeon, Massachusetts Eye and Ear Infirmary; assistant in otology and laryngology, Harvard Medical School.

of such a program. The Foundation is most grateful for the co-operation of all who have made this beginning possible: the clinic staff, the social-service staff, the three highly trained teachers who volunteered their services so that the technics of therapeutic teaching might be worked out, the several hearing aid firms who have met the special needs of the project so efficiently, and all who have referred these young people to the clinic.

On the basis of experience at the Winthrop Foundation, the following problems are briefly discussed: the gravity of the handicap as it appears in the cross-section of New England children studied; the hearing study and its adaptation to the different age levels; and the program for remedial guidance and its adaptation to meet the needs of the individual child.

Gravity of Handicap

A hearing defect of any degree, even the slighter deviations from normal, may be seriously handicapping in early childhood, because of the vital part that hearing plays in the child's speech-language development, in his early intellectual growth and, later, in his education.

His first efforts at speech are an imitation of what he hears. If the sound of voice fails to reach him, he will not develop speech until taught by visual and kinesthetic methods.* If speech is a blur of confused sounds to him, his first efforts at imitation will be delayed and quite imperfect, but will gradually improve as he learns to listen more carefully. His first words may consist largely of vowel sounds. If, as in children with some of the slighter high-tone deviations, he fails to hear only the soft, high-pitched consonant sounds, these sounds will be added slowly and imperfectly, and he may substitute one consonant for another. Frequently, the speech defect so predominates the picture that the underlying hearing impairment may go unrecognized for a number of years.

The young child with even a slight reduction in hearing ability increases his vocabulary more slowly than his normal playmates, and may seem in various ways retarded because of the restriction of his auditory field, even though he has a good intellectual endowment. The child whose hearing distance is only two or three feet misses all the innumerable opportunities of acquiring new words and new facts that make the young child's mental growth so incredibly rapid. If the hearing distance is increased, an intelligence quotient, based to any degree on an understanding of language, is often raised in a short time.

Too much can scarcely be said about the handicapping effect of a hearing disability of any degree

during school years. Such disabilities certainly rank high among the tragedies of school children at present. They are one of the principal causes for the repetition of grades. They are responsible for many of the behavior problems of childhood and adolescence. The child may have been taught to read the lips, but he still loses his place when the children behind him are reciting; he fails to understand the spelling words or the test questions, if the teacher happens to move to another side of the room.

It is therefore apparent that, from the age of twelve months and on through the preschool and school years, a hearing impairment of any degree is a serious disability, and even the slighter ones are far more handicapping than similar degrees of impairment occurring for the first time in adult years. The adult has years of experience in listening, and is often able to supply the word or sound that he does not quite hear, whereas the child is constantly being presented with unfamiliar words and strange new facts.

In addition to the effect of the handicap on early development and education, many pleasures are denied the child with a partial hearing disability—all the soft sounds indoors and outdoors, such as the singing of birds, the chatter of children, the rumble of the city traffic and the sound of a distant airplane. It is hard to forget the eagerness of a little boy who rushed to the door during his first hearing-aid demonstration and stood enthralled at the sound of the cars whizzing by—or of the five-year-old girl who was so surprised at the sound of the chatter of the other children when she first wore her hearing aid to kindergarten.

Hearing Study

To evaluate the child's hearing defect in terms of hearing ability and disability, which may serve as a basis for the clinic remedial program and for interpretation to the family and the teacher, the hearing test has been converted into a hearing study.

For the *child of school age*, one must know not only the character and degree of the hearing impairment in terms of a pure-tone audiometer test by air and bone conduction and of tuning-fork tests, as described by Dr. Mueller in the preceding paper, but also the amount that he is handicapped in hearing of monosyllables, sentences and new school material, such as he might have in school the next day. This estimate is made in two ways: by a phonographic attachment to the audiometer, the amplification necessary in each ear for the child to hear a list of fifty words correctly is determined; and by voice, his unaided binaural hearing for

*This group constitutes a very small proportion of the total number, and is provided for in schools for the deaf.

words, sentences and school material is studied and his hearing distance for different types of material, as well as for individual speech sounds, is established. In this way, one can determine how much difficulty the child has, when he is unable to read the lips of the teacher or of the child who is reciting behind him. All these procedures are necessary, because throughout the years of childhood, there is often not a perfect correlation between the pure-tone test and the interpretation of words heard, which is a function of the higher cortical centers. These various technics are adapted to the age level of the child. Speech defects are recorded as noted. The hearing study is an excellent opportunity for interpretation of the child's difficulty to him and later to his parents.

For the *preschool child*, the entire study is carried out in a nursery-school setting, with play material and with an observation and play-conditioning technic. The child's spontaneous responses to voice, music and a number of gross sounds of different pitches are first studied, and then his trained response, by conditioning him to "pump a ball" or "jump a horse" when he hears a bell or a drum tap. Later, the same procedure is used with the word "pump" or "jump," and in this manner his hearing distance for conversation and whispered voice can be determined, even though he has only a limited understanding of language or none at all. A word-picture game is used for the study of his interpretation of language, and speech is encouraged by play telephone conversations. The audiometer test is introduced as early in the program as possible. A word-picture method is often used up to the age of eight years for study of the child's ability to hear speech.

Remedial Guidance

No one group of the major handicaps calls for more highly individualized remedial programs, based on a detailed study of the child's ability and disability, than the hearing defects of childhood. Yet in no group has the remedial program been more generally routine. The day is past when the routine recommendation of lip reading to every child with a hearing handicap is sufficient. The clinic's duty is not completed at that point: these children deserve the best that medicine and science can give them, and their future happiness and efficiency depend on the proper remedial program at the proper time.

The initial rehabilitation should be considered a therapeutic procedure, growing out of the individual child's needs as evidenced by the cumulative study of his abilities and disabilities in hearing, speech and language during the period of clinic observation, study and therapeutic teaching. The

preschool child remains a rehabilitation problem until satisfactorily launched on his school career. The child of school age should remain a clinic rehabilitation problem until he and his parents understand the nature of his handicap and until he has gained self-confidence and become master of the situation by realizing that he is on the road to better hearing. In the clinic, the child is willing to discuss his difficulties, because he comes to tell his troubles, and it is one's responsibility to see that he is equipped to overcome them to the greatest possible degree. In school, he tends to make light of his handicap, and various behavior problems grow out of his effort to cover his real sense of inferiority.

The majority of these children can be given better hearing and, through better hearing, can acquire better speech, better language and an equal opportunity for school progress and for happiness in and out of school. How is one to accomplish this?

When hearing begins to fail, the eye naturally begins to help out the ear by interpreting some speech sounds through watching the movements of the lips. The soft consonant sounds, which are usually the most difficult to hear, are the easiest to interpret on the lips. Therefore, the eye should always be trained to help the ear whenever there is a permanent hearing defect sufficient to interfere with the hearing of speech. Lip reading is thus one of the first of the remedial measures advised, but it should always go hand in hand with the greatest possible use of hearing, so that a hearing aid, as well as lip reading, is advised when the unaided ear cannot easily hear the louder speech sounds. It has been proved conclusively that sight and hearing together give the highest percentage of speech intelligibility at every age level. In addition to these measures, children whose hearing handicap has been present during early childhood need help with speech and language.

For the *slighter hearing defects in children of school age*, lip reading should be recommended if the child's audiogram shows a persistent loss of between 20 and 30 decibels in the speech range, or if his hearing distance for monosyllables, sentences or new school material is less than 20 feet. This will usually be sufficient for the child whose loss occurs at the age of twelve years or over, and he can proceed with the study of lip reading at school, with instructions to return to the clinic for periodic hearing check-ups and further advice concerning remedial measures, if the hearing impairment proves to be progressive. As always, parent and child are made to realize that hearing, like vision, teeth and general health, should be

checked at intervals, that good hearing is one of the most precious endowments and to be carefully guarded, but that the deviations from normal hearing are no rarer than visual defects and that a hearing defect should never be a cause for hypersensitiveness. For children from six to twelve years old, listening exercises on a game basis should

weeks, he is ready to wear his hearing aid to school and to continue the study of lip reading at school. The class is therefore a revolving one, with a nucleus of old pupils and new ones entering whenever they come to the clinic.

Such a program has proved to be the only satisfactory way of meeting the psychologic and tech-

FIGURE 1.

This photograph shows a group of children having their first training in listening with hearing aids

be encouraged. Many of these children acquire auditory inattention, because conversation at a distance becomes blurred to them. Parents often describe them as "heedless." They should be advised to make listening fun for the child, and the child himself should be urged to listen carefully.

For the *hard of hearing and partially deaf group over twelve years of age*, whose audiograms show a persistent loss of more than 30 decibels in the speech range, and whose hearing distance for monosyllables, sentences and new school material is less than 15 feet, a vacuum-tube hearing aid, the study of lip reading and attendance in a clinic class are recommended. In the clinic class, which is taught by a lip-reading teacher, the child has an opportunity to see other children using aids; he gains practice in adjusting his aid and in combining sight and hearing satisfactorily through exercises, guessing games and pleasant conversation. Most important of all, he has a good time, gains self-confidence, and is better able to cope with his handicap. After attending the class for six to eight

nical problems of adjustment to the new vacuum-tube aids, and the plan is in accord with therapeutic training classes for other types of disabilities in children and young people. Many in the group from twelve to eighteen years are now wearing their hearing aids satisfactorily in school and for outside work and social activities. The majority acquired a hearing distance of at least 20 feet with their aids. In some cases, the remedial program has prevented impending school failure and has made it possible for a high-school boy or girl to go on with his or her chosen line of training. Every effort is made to help this group overcome their hypersensitiveness, and the things to be done to acquire better hearing are constantly stressed, rather than the seriousness of the handicap. As the program for better hearing has grown, parents, children and young people have helped spread this feeling of hopefulness to the newcomers. Despite the combined efforts of the clinic and social-service staffs, however, some parents and some children and young people refuse to accept the idea

of a hearing aid. For them, there are psychological obstacles that will be overcome only through the further education of the public to the fact that today a large majority of the children with hearing handicaps can be completely rehabilitated, and that a hearing aid is by no means a sign of lowered efficiency or ability.

The *hard of hearing and partially deaf group six to twelve years of age* present more complicated individual remedial problems. Many have developmental, high-tone defects with the characteristic speech defects and varying degrees of retardation in language development. Some have conduction losses going back to early childhood, with a large amount of rapid but imperfect speech. Many of these children were late talkers, and have continued to reproduce speech imperfectly as they have heard it. These children need the stimulus of clinic class work (Fig. 1), as described above, but they also need individual instruction in speech correction, lip reading and listening exercises by a specially trained teacher. After several months of weekly clinic training, both individual and group, these children are ready to wear their aids satisfactorily in school, and should be able to proceed in public school with the help of special lip-reading instruction, which many school systems provide. A number of these children, without the benefit of a hearing aid and the intensive remedial clinic program, would have been obliged to transfer to a special school for the deaf. It is hoped that a considerable group are being completely rehabilitated. This means that some children will be able to remain in their own homes and in regular classes who formerly were transferred to special boarding schools at considerable expense to the State. Such programs, therefore, organized on a larger scale, can be measured in terms of greater happiness to a group of children and parents, greater efficiency in the coming adult generation and an appreciable financial saving to the State.

The *preschool group* present very special remedial problems. The preschool child with only a slight hearing handicap may have very poor speech, and is usually a very poor listener. At certain times during the day, he may seem not to try to listen. Speech may be so blurred and confused to him that he does not make the effort to listen when he is tired. If his hearing distance for familiar words is 10 to 12 feet, he should be trained and encouraged to listen through games and exercises, which he will enjoy. His imperfect speech sounds should be corrected through hearing to as great an extent as possible, and he should have some training in lip reading, but with emphasis always on the combination of sight and hearing. His clinic program should consist of both group

and individual work, and the listening exercises and games should also be carried out at home.

For the partially deaf preschool child, who has developed a small amount of imperfect speech and who has a hearing distance of from 2 to 12 feet for familiar words, a hearing aid, in addition to in-

FIGURE 2.

This photograph shows how learning to listen and to lip-read are made fun for young children.

dividual training in listening, lip reading and speech correction through hearing, is recommended. Again, the stress is placed on a combination of sight and hearing. The entire program, from the hearing study throughout the training period, is carried out on a play-school basis. The group class often seems like a party to these younger children (Fig. 2). The hearing aid is first introduced as a play telephone, and a word-picture game is used for measuring its usefulness at various distances.

A five-year-old girl has been wearing an aid the entire day for six months. She has worn it in kindergarten as unconsciously as a child might wear a pair of glasses. Her hearing distance has been increased from 2 feet to 15 feet, and she has

lowered the pitch of her voice, corrected her own imperfect speech sounds, and increased her vocabulary from about thirty words to sufficient language to carry on a normal conversation for her age. She is now able to take part in games, whereas formerly she stood on the outside and watched. Being fitted to an aid at just this crucial moment, she should have a normal school career and a much happier, fuller childhood.

If the age of rehabilitation can be lowered to three years, still more of the critical years of early childhood may be retrieved, and speech and language may be acquired more completely in those years of greatest speech readiness. The detection, evaluation and correction of hearing disabilities during preschool years are a major aspect of the entire problem. A year of childhood lost can never be completely regained. The child is normally most ready to acquire speech and language during his second, third and fourth years, and should be ready at six years to grasp new material rapidly through his hearing. More stress should be placed on the hearing readiness of children before they enter school, and greater efforts made to cor-

rect, through proper remedial measures, defects that cannot be cured through therapy. As the mother of a five-year-old child said, "Next to complete restoration of hearing, H——'s complete adjustment to her hearing aid is the nicest thing that could have happened to us."

SUMMARY

With increasing emphasis on the early discovery of physical defects in children, a great need arises in the field of otology for the development of intensive clinic programs for the detailed study of the abilities and disabilities of children with hearing handicaps, adapted to the different age levels, and for the development of programs of therapeutic remedial guidance, based on such individual studies. The majority of children with hearing handicaps are potentially normal, if found early and adequately rehabilitated. Better hearing is now a possibility for most of these children, and, because of this, better speech, better language and an equal opportunity for progress in school and for happiness in and out of school.

THE WORK OF THE BOSTON GUILD FOR THE HARD OF HEARING

EUNICE ACHESON PUGH*

BOSTON

IMPAIRMENT of hearing is a serious physical defect as well as a social, economic and vocational handicap to a vast number of people. Surveys throughout this country indicate that there are approximately 15,000,000 persons at the present time with some hearing deficiency. This figure includes those with only a mild hearing deficiency and a large number of younger persons who readily respond to treatment. Nevertheless, it leaves several million with a permanent and serious hearing loss who cannot be helped medically and who are in real need of readjustment.

Many of these are hopeful cases, owing to the availability of agency services and a better understanding of hearing problems. It is therefore of real value for physicians to know about the local centers that serve deaf people and to become more familiar with the programs that enable the hard of hearing to remedy and surmount their difficulties.

The Boston Guild for the Hard of Hearing, located at 283 Commonwealth Avenue, is a social agency operated by and for the hard of hearing of

Metropolitan Boston. It offers its services not only to its members but also to the community by helping the person with a hearing loss to develop his remaining capacities and to make adjustments along a number of concrete lines.

One outstanding activity of the Guild is hearing-aid guidance service. The first step taken when a person comes for help is to study his particular case. To do this, several pertinent questions are always asked. Has he received adequate care from an otologist and has his hearing been given all the benefit of medical treatment? If not, medical advice is recommended either by an ear specialist of the patient's choice, by one of the Guild's consulting otologists or by the service of a dispenser, as the case indicates. Many persons are referred directly from physicians or hospitals, and in these cases a summary is frequently sent in advance. The second question asked is, What is the degree and character of the hearing loss? If this has not already been determined by an otologist, the Guild is prepared to make an audiogram, using a standard audiometer. If it is found that a person will be benefited by and is able to finance a hearing

*Executive secretary, Boston Guild for the Hard of Hearing.

ing aid, the next question is, Which of the several types and makes are most suitable? Laboratory evaluations of these instruments are not available to the average purchaser, but the only instruments in the Guild demonstration collection are those approved by the Council of Physical Therapy of the American Medical Association. It is believed that there is no best hearing aid for everyone, and an hour's comparison of the various instruments is an effective means of deciding which device assists the patient to make use of his impaired hearing to the fullest possible extent.

After one of several hearing aids is selected as giving the best results, the person is advised to consult the company where the instrument may be tried out and purchased. Every year, an increasing number of otologists and general practitioners refer patients to the Guild. This service aids the physician in overcoming the patient's habitual resistance to wearing a hearing aid and is a help to the person bewildered about which instrument to purchase among those so widely advertised.

In addition, the Guild has a few hearing aids that are available as loans to persons who are prevented by hearing difficulties from obtaining and maintaining employment and who have no means of financing an instrument.

Lip reading is another means of rehabilitating the deafened. Almost anyone whose vision enables him to see a speaker's lips at a distance of three or four feet can learn something about lip reading. The amount he learns depends on his attitude toward his handicap, his perseverance and his regular attendance at classes. The slightly hard of hearing can profit fully as much as the severely deafened and should be urged to take up the study of lip reading early, for this skill develops only gradually and with much practice. Hearing aid salesmen often say that the most successful users of instruments are those who have learned to concentrate their attention on the speaker's mouth as a result of lip reading lessons. It is therefore essential to stress the study of lip reading as well as the use of a hearing aid. The former also offers a solution to the person who cannot be helped medically and who is unable to hear with an audicle. Lip reading bridges the gap for the person whose loss is not severe enough to warrant the use of a hearing aid.

The Guild is not a school of lip reading, but gives classes in practice and drill, so that anyone who wishes to master the art is urged first to take private lessons from qualified teachers. It has free afternoon and evening classes, however, for those who cannot afford tuition elsewhere.

Another service is conducted for children with hearing difficulties by the giving of audiometer tests. Parents are also advised about adequate educational provisions for the child who is so handicapped. Always alert to outside contacts, the Guild interests school and health authorities in hearing tests for school children so that preventive and helpful measures may be taken in time. It owns a 4C audiometer, especially designed for the testing of school children in groups of as many as forty, which is available to any public or private school on the payment of a small upkeep charge. A trained audiometer technician on the Guild staff is also available to do this testing in the schools.

Massachusetts has its own department of vocational rehabilitation and a division for the hard of hearing under a trained social worker, who co-operates with the Guild in securing retraining and employment for many people.

The Boston Guild is also a service club offering a varied social and educational program to its members. This was founded on the premises that the isolation of the hard of hearing is largely responsible for traits often attributed to them—sensitiveness, suspicion, lack of courage and initiative—and that the cure lies in the removal of the cause. Entertainments, lectures, card parties, teas, out-of-door trips and gatherings for various other purposes provide incentive for people who are hard of hearing to get together and make new friendships. *Special facilities, including a group hearing aid in the auditorium at the Guild House, make the programs easily available for the members.* Men are encouraged to join a very active men's club, and young persons find worthwhile outlets in the young people's group.

The Guild also offers opportunity for growth in personality and creates normal outlooks with the right perspectives on impaired hearing. Otologists with patients who are isolating themselves and who need a better attitude toward their handicap would do well to recommend membership in the Guild. Those who wish this privilege, however, should not belong to the deaf group, since facilities for them are provided elsewhere. Nevertheless, any deafened person may make formal application for membership at the Guild if he furnishes the necessary references.

Many people with normal hearing, among them physicians, not only support the Guild's work but become members. In no other way can they understand the urgent problems of hearing that are rapidly becoming more crucial in modern society.

The Boston Guild for the Hard of Hearing is supported by membership dues, by rent from rooms

in its house, by voluntary contributions from members and friends, by interest from endowments and by participation in the Greater Boston Community Fund campaign.

During National Hearing Week, the last full week in October, the local chapters bring their work and that of the American Society for the Hard of Hearing to the attention of the general public by radio talks, lectures, pamphlet material, posters, demonstrations of lip reading and publicity

of various kinds. Otologists and physicians are welcome to any of these activities.

There are eleven leagues for the hard of hearing in Massachusetts and thirteen in four other New England states, all of which are constituent chapters of the American Society for the Hard of Hearing and work actively in the interests of persons so afflicted.

283 Commonwealth Avenue

CASTRATION FOR CARCINOMA OF THE PROSTATE*

Report of Forty-One Cases

C. H. NEUSWANGER, M.D.,† AND VINCENT VERMOOTEN, M.D.‡

NEW HAVEN, CONNECTICUT

THE report of the effect of castration on carcinoma of the prostate by Huggins et al.§ before the meeting of the American Urological Association in June, 1941, at Colorado Springs so impressed us that we have urged all our patients with carcinoma of the prostate to permit a bilateral orchidectomy. To date, we have operated on 41 of these patients, none of whom, up to the present, have regretted having the operation done. One patient died of pneumonia five months after operation. In the remaining cases, there are no complaints. On the average, the patients gained a minimum of 5 pounds in weight, and many as much as 20 or 30 pounds. The most striking changes observed were a marked increase in appetite, complete relief of pain, improvement in bowel habits and a feeling of well-being. There was also complete relief of urinary symptoms, but all patients except 1 had also had a transurethral resection of the prostatic carcinoma, which, no doubt, contributed considerably to this improvement as well as affording an opportunity to confirm the clinical diagnosis.

Our observations substantially confirm those reported by Huggins and his co-workers, even to the almost miraculous response of one patient who had a paraplegia resulting from a metastatic lesion in the spine.

In the following cases, the results were striking.

CASE REPORTS

CASE 1. G. A. P., when first seen in March, 1940, was found, on rectal examination, to have a carcinoma of the prostate. Except for nocturia once and some slight day frequency, he had no symptoms of note. In May, 1941, the nocturia had increased to three or four times, and the fre-

*Presented at a meeting of the New England Section of the American Urological Association, Boston, February 12, 1942.

§Huggins, C., Stevens, R. E., Jr., and Hodges, C. V. Studies on prostatic cancer. II. The effects of castration on advanced carcinoma of the prostate gland. *Arch. Surg.* 43:209-223, 1941.

quency during the day to once every hour or so. The patient was not seen again until the end of September, 1941, when he had developed complete retention of urine, with overflow incontinence. He was immediately admitted to the hospital.

Rectal examination showed a huge prostatic carcinoma, which had occluded the urethral lumen to such an extent that it was not possible to pass even a filiform guide through it. Bilateral orchidectomy was done the next morning, no attempt being made to relieve the urinary retention.

Within 48 hours, the patient was voiding small quantities spontaneously, and by the end of a week, the bladder, which had previously been distended to the umbilicus, could not be felt or percussed above the symphysis. At present, the prostate is greatly reduced in size, although not yet within normal limits. The patient is able to empty his bladder completely and voids only twice at night. He has gained 22 pounds in weight and is symptom free.

CASE 2. L. J., a 77-year-old man, was seen during the latter part of November, 1941, complaining of priapism, which had begun about 3 months previously and was continuing for longer and longer periods without relief. He had no other symptoms or discomforts except that he claimed that intercourse made the priapism worse and more painful.

Rectal examination revealed a large, hard, nodular, carcinomatous prostate.

Following a transurethral resection (to obtain tissue for microscopic examination) and a bilateral orchidectomy, the priapism gradually subsided until the 4th postoperative day, when the penis was completely flaccid, in which condition it has remained ever since.

CASE 3. D. M. D., a 76-year-old man, was admitted to the hospital for relief of respiratory distress in September, 1941. In March, 1936, one of us (C. H. N.) had operated on him, doing a radical prostatectomy and seminal vesiculectomy for carcinoma. Since that time, he had been considered cured. It was learned, however, that owing to marked respiratory distress he had been bedridden for 3 months.

On admission to the hospital, the patient was practically moribund. X-ray examination revealed that the lung fields were riddled with metastatic carcinoma, as were the bones of the pelvis, the lumbar and dorsal portions of the spine and the ribs. The patient had no urinary symptoms, and there was no local recurrence of the carcinoma.

Since it was assumed that the metastatic growths were from the old prostatic carcinoma, a bilateral orchidectomy was performed under local anesthesia. The general condition rapidly improved, so that the patient was able to go home at the end of 2 weeks. Five months later (operation), he was up and about most of the day doing odd jobs about the farm. His general health was greatly improved, and the respiratory distress almost gone.

CASE 4 W W, a 55 year-old man, was first seen on December 1, 1941, complaining of girdle pains which radiated from the back around and forward to the umbilicus, of 9 months' duration. These pains were noticed whenever he bent forward or stooped to lift anything. Soon, he noticed that the pain was more marked along the lower costal margin and he began to have aches and pains in the arms and shoulders as well. He thought this was due to nervousness and worry as the result of the death of his son. On the advice of a friend he consulted a chiropractor, who manipulated him for one course of thirty five treatments and a second course of twelve during June, July and August. Since he did not get a great deal of relief, he was advised to have his teeth extracted. In September, he was sure it was all nerves and therefore consulted a neurologist, who had him admitted to the hospital for examination. Neurologic examination was essentially negative, but x ray films revealed several dental root abscesses and widespread osteoplastic changes throughout the spine, pelvis and bony thorax probably metastatic from a carcinoma of the prostate. After having all his teeth extracted, the patient was sent home with the advice to his physician to give him what sedatives he might need.

Early in October, he began to notice frequency of urination and a month later found that he was not able to use his legs very well. He staggered when walking, and his legs felt weak. This condition gradually got worse until November 15, when, on returning home, he found that he was unable to climb up stairs. He was put to bed and soon discovered that, although he had a great deal of pain and tenderness along the lower rib margin, he had no feeling whatsoever from the waist down. He was unable to move his legs, which felt dead, and when he attempted to move them his wife noticed that they were quite stiff. The next day, he was unable to urinate and therefore called his physician, who catheterized him. This was done twice a day until admission to the hospital on December 2.

On entry, the patient had a spastic paraplegia, with complete loss of sensation to pinpricks from the waist down. There was a band of hyperesthesia just below the costal margin, and he was unable to distinguish between heat and cold on the left side.

On December 3, a transurethral resection of the prostate and a bilateral orchidectomy were done. The catheter was removed on the 4th day after the resection and the patient was subsequently able to void spontaneously. The bowels moved voluntarily, whereas before operation they moved only with an enema.

Two days after orchidectomy, the patient noticed involuntary twitching of his legs, with occasional jerking movements. A week after operation, there was a beginning return of sensation and some slight voluntary movement of the legs. Two weeks after operation, he had almost complete return of sensation from the waist down, and the area of hyperesthesia had practically disappeared. He was also able to move his legs freely in bed. A week later, he was up and walking about with crutches and had complete urinary and bowel control.

When seen on February 10, 1942, the patient had gained 25 pounds in weight. He was able to walk about wherever he pleased with the help of a single cane, which he considered unnecessary. He had no pain or discomfort anywhere, even on bending. He emptied his bladder completely, voided once during the night and once every 3 or 4 hours during the day. Neurologically, we could determine no sensory changes in the lower extremities. The muscle tone was good, and his knee jerks were equal and active. A mass of supraclavicular lymph nodes on the left, which were large, hard and readily palpable when first seen in December, are now definitely much smaller, and the prostate is considerably reduced in size. Microscopically, the tissue resected was reported to be adenocarcinoma of the prostate, Grade II.

Comparing the x ray films taken 2½ months before orchidectomy with those taken 2 months after operation, one sees that all the lesions became much denser, giving the impression that the disease had become more widespread despite the very marked clinical improvement.

SUMMARY

A report is given on the early postoperative effects of bilateral orchidectomy and transurethral resection on 41 patients with carcinoma of the prostate. Four very striking cases are reported in detail.

PREMONITORY SYMPTOMS OF MYOCARDIAL INFARCTION*

NORMAN H. BOYER, M.D.†

BOSTON

SINCE 1912, when Herrick¹ first described the characteristic signs and symptoms associated with infarction of the myocardium, atypical cases have been recognized with gratifying frequency. Knowledge of the pathology, physiology and pathologic physiology of the coronary circulation continues steadily to advance. The treatment of myocardial infarction, once it has developed, is better understood and more generally applied. Knowledge has apparently progressed to the point where it may now be profitable to turn attention toward recognition of the premonitory symptoms of myocardial infarction in the hope that the institution of therapeutic measures may diminish the severity of the illness or even, in some cases, prevent clinically recognizable infarction entirely.

In a certain proportion of cases, probably a larger number than has been suspected, the onset of myocardial infarction is not sudden and unpredictable but is preceded, for a variable time, by premonitory symptoms, which should receive more serious and general attention. The following cases will serve to indicate some of the danger signals of impending myocardial infarction. Some of the cases furnished a hopeful hint that favorable effects may be expected by prompt recognition and institution of measures designed to increase the absolute or relative coronary blood flow.

CASE 1. A 58-year-old man had noted slight exertional dyspnea for about a year. For 3 months, he had had mild substernal pain, usually after meals. He then began to have attacks of severe, crushing substernal pain, not related to effort and lasting 2 or 3 hours. He had four such attacks in the course of a week. He was seen by his physician several times during that week, and each time the electrocardiogram, white-cell count and erythrocyte sedimentation rate were within normal ranges. Other studies revealed no extracardiac cause for the pain. The patient was advised to go to Florida for a vacation, but 2 days later, he developed a severe attack of pain lasting 8 hours. With this attack, he went into collapse and remained in "shock" for 3 days, with oliguria and rising blood nonprotein nitrogen. The development of fever, leukocytosis (a white-cell count of 18,000) and characteristic changes in the electrocardiogram confirmed the diagnosis of acute myocardial infarction. The course was somewhat stormy, with paroxysmal auricular fibrillation and at least one splenic infarct. However, after 8 weeks in bed and 2 months more of easy convalescence, the patient made a good recovery and has been well and active for the past 2 years.

In this case, the significance of the repeated prolonged attacks of chest pain during the week preceding acute infarction was not at the time fully appreciated. The duration of the pain seemed to the physician in charge to be too long for angina pectoris, and the absence of fever, leukocytosis and electrocardiographic changes apparently eliminated infarction. It was concluded, therefore, that the heart was not the seat of the pain. Had more attention been paid to the preceding story of substernal pain after meals, it is likely that the prolonged attacks would have taken on new significance. Prolonged substernal pain, with or without characteristic radiation and with or without antecedent angina pectoris, should, in the absence of other obvious causes, be regarded as due to sudden narrowing or closure of a coronary artery. Care must be taken, of course, to avoid confusion with acute coronary insufficiency induced by tachycardia or some other cause.

It is still not widely enough appreciated that the clinical evidence on which proof of the diagnosis of acute coronary occlusion depends consists in manifestations of actual infarction of the muscle. Coronary occlusion and myocardial infarction are not synonymous terms; either may occur without the other, but it is only infarction that produces fever, leukocytosis, changes in the electrocardiogram, friction rub and so forth.

CASE 2. A 58-year-old man, whose family history was unfavorable inasmuch as his mother had died of angina pectoris at 53 and his father of coronary occlusion at 55 years of age, suddenly developed, on March 4, 1941, discomfort over the precordium, with radiation to the back and to the neck. On one or two previous occasions, a similar but less severe and less prolonged pain had occurred. The patient was admitted to the hospital within an hour of the onset, but the pain persisted for several hours despite bed rest and morphine. Physical examination was negative except for occasional premature beats. During the first day in the hospital, two intramuscular injections of papaverine hydrochloride, ½ gr., and atropine sulfate, 1/100 gr., were given at four-hour intervals. Two days later, the pain returned for a few moments following a bowel movement. The patient was kept at rest in the hospital for 2 weeks, during which there was no fever, leukocytosis or increase in sedimentation rate, and no abnormalities or serial changes in the electrocardiogram. He continued to rest at home for another 3 or 4 weeks and has been well and active for the past year.

This appears to be a case of sudden coronary narrowing or occlusion without definite clinical evidence of infarction. Such cases are being recog-

*From the Evans Memorial, Massachusetts Memorial Hospitals, and the Department of Medicine, Boston University School of Medicine.

†Instructor in medicine, Boston University School of Medicine; assistant physician, Evans Memorial, Massachusetts Memorial Hospitals.

nized with increasing frequency. It seems wise under such circumstances to put the patient at rest, to keep the needs of the heart muscle at an absolute minimum. The use of papaverine is based on its apparent good effects when there is sudden closure of a peripheral artery or embolism to a

Not only must one be alert to the possibility of occlusion or narrowing of a coronary artery, without clinically demonstrable infarction on the corresponding myocardium, but also one must guard against haste and impatience in the management of such patients. Failure to provide an

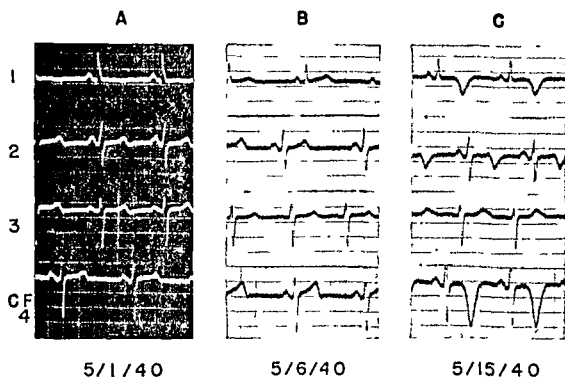

FIGURE 1. Case 3.

Record A was taken twelve hours after a severe attack of substernal pain lasting several hours, there is a considerable degree of left-axis deviation, slight inversion of T_1 and an upright T_3 , with a slightly high origin of ST_3 ; the record was interpreted as indicating left ventricular strain. Record B, taken five days later, shows slight changes in the T waves and ST segments; the record is not definitely abnormal. Record C was taken fourteen days after admission and the day following a trip to the X-ray Department for a gastrointestinal series; the tracing shows marked inversion of the T waves in Leads I, 2 and 4.

pulmonary artery. There is evidence that sudden closure of an artery to any part is often accompanied by reflex vasoconstriction of other vessels to that part. Such reflex vasoconstriction in the heart might well interfere with the establishment of collateral circulation, most if not all of which comes from the unoccluded coronary vessels.^{2,3}

The presence of reflex constriction of the coronary bed following ligation of one of the coronary arteries has been indicated by the experimental studies of Manning, McEachern and Hall⁴ and LeRoy and Snider.⁵ The latter authors were able to reduce the mortality of coronary-artery ligation in dogs by the use of atropine, which they believe interrupted the efferent pathway of the reflex arc. McEachern, Smith, and Manning⁶ were able to show a moderate reduction (from 75 to 50 per cent) in the immediate mortality of coronary-artery ligation following the administration of papaverine in doses rather larger than are ordinarily employed clinically.

adequate period of rest may result in delayed infarction, such as presumably occurred in the following case. It hardly needs to be emphasized that the error of ascribing to the heart pain that belongs in the domain of surgery should be scrupulously avoided. A careful history and good judgment go far toward preventing such an error.

CASE 3. A 61-year-old woman with known hypertension for 12 years had been well except for slight exertional dyspnea until 2 weeks before admission to the hospital, when she developed burning substernal pain on effort and after meals. A week before admission, the pain increased in frequency and severity and even came on at rest on one occasion. The day before admission, the patient walked a mile to her doctor's office and on the way home developed a severe substernal pain, which gradually increased in severity and radiated to the arms. The pain lasted several hours, was only partially relieved by nitroglycerin, and was accompanied by weakness and sweating. On admission, the patient had no pain or other complaints. The blood pressure was 194/90. The heart was regular, the sounds were of fair quality, and there were no murmurs or gallop. The lungs were clear, and the abdomen

and the extremities normal. The temperature was normal, and the white-cell count was 10,000. The sedimentation rate, however, was elevated to 1.1 mm. per minute. The patient remained free of symptoms, fever and leukocytosis for 2 weeks. The electrocardiogram on admission showed slight inversion of T_1 and upright T_3 (Fig. 1). The pattern was thought to indicate "left ventricular strain." Five days later, T_1 had become upright. At the end of 2 weeks, the patient was sent to the X-ray Department for a gastrointestinal series because of the absence of any clear indication of myocardial infarction and because of the previously mentioned relation of the pain to meals. Following her return from x-ray study, she developed more pain, the white-cell count subsequently rose to 13,600, and the electrocardiogram showed deep inversion of T_1 , T_2 and T_4 . There was gradual evolution of the electrocardiogram toward normal in the course of several weeks.

The patient made a good recovery but succumbed to another myocardial infarction 1½ years later.

It seems fairly clear that this patient had coronary occlusion, following a short period of angina pectoris, but without definite evidence of infarction of the heart at the time of admission to the hospital. The untimely trip to the X-ray Department may have precipitated actual infarction of the heart by increasing metabolic demands at a time when the coronary blood flow could support resting needs only. The possibility of a sudden, unrelated occlusion cannot, of course, be summarily dismissed.

CASE 4. A 51-year-old man had always been well and very active. In December, 1941, he developed a mild sense of constriction beneath the sternum while riding horseback. The discomfort lasted a few moments. On two or three subsequent occasions, mild substernal discomfort recurred. On February 16, 1942, he developed a severe attack of chest pain lasting several hours. Fever, leukocytosis, and characteristic electrocardiographic changes established the diagnosis of acute infarction.

This case illustrates the fact, now fairly widely known, that myocardial infarction may appear soon after the onset of angina pectoris.

It seems reasonable to suppose that decreasing the demands on the heart, by bed rest during the critical period when collateral circulation is presumably being established, may have a salubrious effect. The possibility that this may occur is indicated by the following case.

CASE 5. A 69-year-old man had always been well and active until 10 or 12 days before being seen, when he began to have attacks of substernal pain that were brought on by walking and relieved by rest. Later, the pain was induced by eating. On the day of the examination, the pain appeared following lunch and was partly relieved by nitroglycerin, but the patient still had some pain when seen 2 hours later. Physical examination and fluoroscopy of the heart showed no abnormalities. The temperature was 99°F., and the white-cell count 10,000. The electrocardiogram showed depression of the ST segments in all leads (Fig. 2), a common pattern during spontaneous or induced attacks of angina pectoris.

The patient was hospitalized and kept at bed rest for 3 weeks, during which there was no fever, leukocytosis or increase in the erythrocyte sedimentation rate. The electrocardiogram taken 3 days after the first record showed no ST displacement. Another record a week later did, however, show changes in T_1 and T_3 , suggesting that the heart had not entirely escaped damage.

There is, of course, no proof that this patient would not have done equally well if allowed to continue with his usual mode of life, but this seems an entirely unreasonable assumption. Ex-

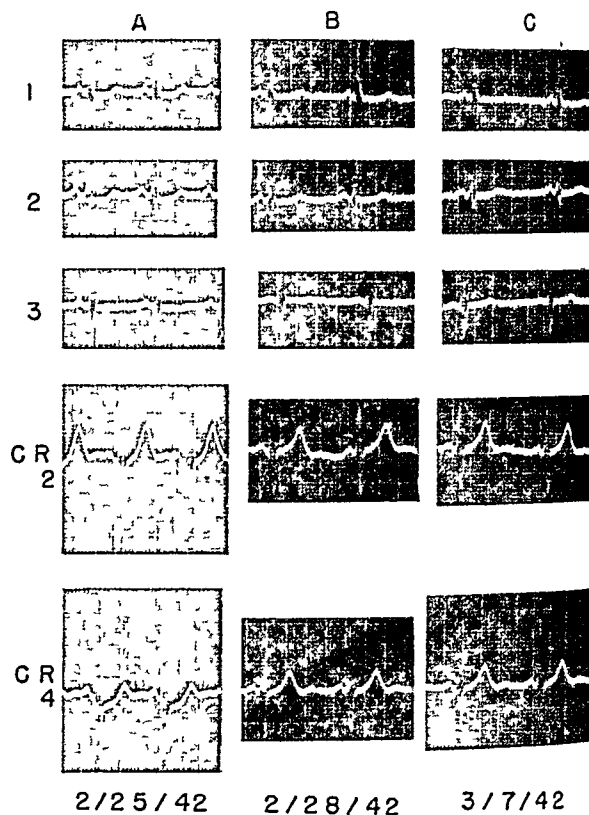

FIGURE 2. Case 5.

Record A was taken during an attack of pain lasting two or three hours; there had been sudden onset of angina pectoris ten to twelve days previously; the record shows depression of the ST segment in all leads. Record B, taken three days later, shows no definite abnormalities. Record C, taken seven days later, shows flattening of T_1 and an increase in the height of T_3 , suggesting that there had been some change in the heart muscle.

perience with other patients who have suffered extensive infarction of the heart soon after the sudden onset of angina pectoris or following prolonged pain (for example, Cases 1 and 4) leads one to expect a similar course in this patient. That such an infarction did not develop can be fairly attributed to lessening the demands on the heart by means of bed rest.

CASE 6. A 60-year-old man, who had had angina pectoris for 5 years, had a sudden increase in frequency and

severity of attacks for 2 or 3 weeks. During this time, the attacks occasionally came on at rest. There was no dyspnea or other cardiovascular symptoms. Physical examination and fluoroscopy of the heart showed no abnormalities. The electrocardiogram showed prolonged auriculoventricular conduction (a PR interval of 0.22 second) and right bundle-branch block. Because of the recent onset

pectoris, and at that time the electrocardiogram was normal. In January, 1941, he again complained of chest pain not characteristic of angina pectoris. The electrocardiogram had changed, however, T_1 being inverted (Fig. 3). The patient was advised to curtail his activities, and after a few weeks the pain disappeared. In December, he was seen again because for the previous week he had had dull

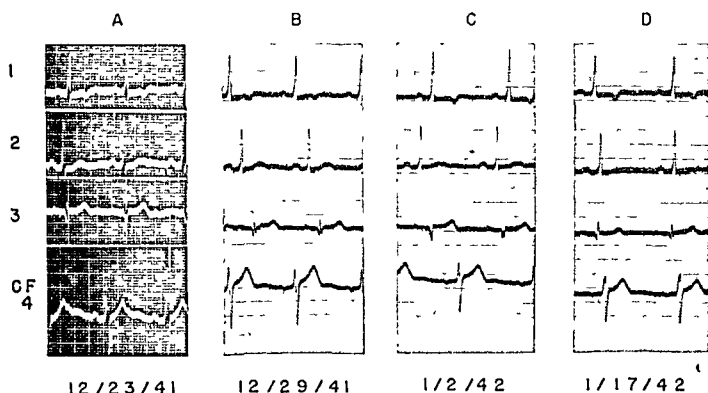

FIGURE 3. Case 7.

Record A, taken one week after the sudden onset of angina pectoris, is identical with one taken eleven months previously; the patient was admitted to the hospital at once because of the symptoms of coronary insufficiency; the record indicates left ventricular strain but not acute infarction. Record B, taken six days later, shows no essential change in the T waves or ST segments, the PR interval, however, has lengthened from 0.18 to 0.22 second. Record C, taken four days later, shows no change. Record D shows slight flattening of the T waves in Leads 2 and 3; the slight T-wave changes and prolonged auriculoventricular conduction suggested that active changes had taken place in the heart.

of increased coronary insufficiency, the patient was advised to go to bed. This he declined to do. Ten days later, he was seized with a severe attack of chest pain lasting 6 or more hours. Serial changes in the electrocardiogram, a temperature of 101°F. and a white-cell count of 18,000 established the diagnosis of infarction. There was marked gallop rhythm, accentuation of the pulmonic second sound, Cheyne-Stokes respiration and persistence of a shocklike state for 2 days. There was an attack of tachycardia, probably of ventricular origin, although there was no graphic proof. After 3 months, the patient was able to undertake moderate activity without symptoms.

Not only the sudden onset of angina pectoris in a patient previously well but also the sudden increase in frequency and severity of pre-existing angina may presage the onset of myocardial infarction. It is reasonable to suppose that reducing the metabolic needs of the heart during this period may avoid such a critical illness as this patient went through, either by preventing infarction or by materially reducing its size.

CASE 7. A 60-year-old man had complained of vague chest pain in 1937. This was thought not to be angina

pain beginning at the back of the shoulders and radiating beneath the sternum. This time, the pain was definitely brought on by exertion and relieved by rest. The electrocardiogram was unchanged from that taken 11 months previously. Physical examination was negative. The patient was put to bed for 2 weeks, and on being allowed up, he developed a moderately severe attack of dull substernal pain lasting 10 to 15 minutes. He was put back at bed rest for another week and then gradually allowed up, without any recurrence of pain. At no time during his hospital stay did fever, leukocytosis or increased sedimentation rate develop. The electrocardiogram, however, showed prolongation of auriculoventricular conduction and slight changes in the T waves, suggesting, as in Case 5, that the heart had not entirely escaped damage.

This is another case in which it is difficult to prove that anything was accomplished by enforced bed rest. The changes in the electrocardiogram indicate, however, that changes were going on in the heart, and it is certainly not unreasonable to believe that such changes were less extensive than they would have been were the patient actively engaged in his usual occupation during this period.

DISCUSSION

The presence of prodromal symptoms probably depends on the rate at which the occlusive process in the coronary vessels develops. Sudden complete closure of a large or moderate-sized vessel will undoubtedly result in immediate infarction of the corresponding myocardium. Atherosclerosis of the coronary arteries is a progressive disease, which is fortunately accompanied by the production of collateral circulation when the need arises. At times, the growth of collateral circulation is unable to keep pace with the progress of the disease, and when the disease is in the ascendancy, symptoms appear or increase. When symptoms are present, indicating that the disease is progressing rapidly, such as the sudden increase of angina pectoris and the onset of prolonged pain, it seems only reasonable to keep the metabolic demands of the heart at a minimum by strict bed rest. In all ischemic tissue, there must be a peripheral zone in which the balance of supply and demand of blood is at a critical point. A little more or less blood or a little more or less demand may mean the difference between viability and death of the tissue. Thus, one might at least expect that, even if infarction occurs, its size may, in some cases, be reduced by virtue of reduction in the demands of the peripheral zone under conditions of absolute rest. If the occlusive process develops slowly enough or if the area affected is small, necrosis of the muscle may not occur.⁹ There would seem, therefore, to be little room for doubting the advisability, on theoretical grounds, of minimizing the demands on the heart at a time when symptoms suggest that its blood supply is inadequate, but whether or not any tangible benefit accrues is difficult to evaluate.

Sampson and Eliaser⁷ have recorded their experience with the frequency of prolonged attacks of pain, preceding by an interval of days or weeks the onset of infarction. They observed premonitory attacks in 29 patients. Seven patients who were put at bed rest developed infarction despite this precaution, and the mortality rate was not significantly different from that in the remaining patients, who were allowed up and about during the interval between the onset of the premonitory pain and the onset of the infarction. However, they emphasized that the series is too small to allow any conclusions on this point. They had observed 6 other patients, with a single prolonged attack of pain, who were put at bed rest and subsequently did not develop myocardial infarction. They were unwilling to believe, without further proof, that infarction had actually been forestalled. It is true that convincing proof is difficult to obtain, but cases such as Cases 5 and 7, in which slight

changes occurred in the electrocardiogram, indicate that changes were occurring in the heart muscle, and it is not unreasonable to assume that such changes might have been more extensive had the demands on the myocardium been greater during this critical period.

Feil⁸ also calls attention to the frequency of preliminary pain in myocardial infarction. He states that the pain recurred for an interval of from twelve hours to four weeks preceding infarction, and that he encountered it in 50 per cent of patients with myocardial infarction. He further suggests the point, which needs strong emphasis, that *a normal electrocardiogram does not rule out a developing infarction*. He recommends moderate restriction of the activities of patients during the stage of preliminary pain, but, in view of the gravity of the situation, this seems an inadequate compromise. Complete bed rest under these circumstances has also been urged by Blumgart, Schlesinger and Zoll.⁹

The enforcement of two to four weeks in bed for the patient in whom there is no proof of impending infarction, or proof that the patient will benefit in any way from a period of enforced rest may seem to be radical treatment. Balanced against the possible death of the patient from acute infarction, a prolonged illness extending from three months to a year or more, chronic invalidism, or, at best, a heart with a large myocardial scar, two or three weeks in bed, *if there is the least hope of preventing these sequelae*, seems conservative treatment.

The length of time required in bed varies from case to case. There is experimental evidence that effective collateral circulation requires from one to three weeks for its development.^{10, 11} Thus, as a starting point, two weeks should be considered the minimum length of time. It can then be lengthened, if necessary, depending on the patient's response to gradually increasing activity.

It is not suggested that all patients with angina pectoris need be put at bed rest, although even here there is evidence that a period of bed rest at the start of treatment of all patients with angina pectoris may do great good.¹² It is when symptoms of a sudden increase in coronary insufficiency develop that enforced bed rest is urged.

Emphasis has been placed on bed rest, but it is clear from the report of Sampson and Eliaser that rest alone does not prevent infarction in all cases. Other general measures should not be neglected. Primary among these are sedation and avoidance of tobacco. Cognizance should be taken of the increase in cardiac work incident to large heavy meals, and the dietary should be arranged around light foods in small amounts. Drugs al-

leged to dilate the coronary arteries occupy a position of secondary importance. There are reasons for believing that the stimulating effect of the xanthines may be undesirable.¹¹ Papaverine may be used for its possible effect on overcoming spasm in unaffected vessels that serve as the source of supply for the collateral circulation. Although it has been shown that the maximum collateral flow occurs only after several days or weeks, an immediate increase,¹⁰ although slight, may conceivably keep all or part of the ischemic myocardium viable if such collateral flow is not hampered by reflex constriction of the vessels that provide the source for collateral circulation and if, at the same time, the metabolic needs of the heart are minimized. Atropine may also be used on the basis of previously cited experimental work, although the tachycardia incident to its use may not be altogether desirable. So far as is known, papaverine has no undesirable effects on the heart.

SUMMARY AND CONCLUSIONS

Sudden onset of angina pectoris, sudden increase in the severity and frequency of pre existing angina pectoris, and prolonged chest pain without signs of cardiac infarction have been found to precede the onset of infarction in some patients.

Recognition of these warning symptoms and proper treatment by rest, sedation, avoidance of

tobacco and the use of papaverine may, in some cases, reduce the size of the eventual infarction or possibly forestall it entirely.

PROTEINURIA AND THE ASSOCIATED RENAL CHANGES^{*}

WILLIAM DOCK, MD†

NEW YORK CITY

THE first observers of proteinuria, Dekkers (1694) and Cotugno (1765), theorized that it should occur in certain conditions, made a single observation that happened to verify their erroneous theories and thus missed the true significance of the phenomenon.¹ Cruikshank, Wells and Blackall² first made systematic studies, and by 1827, John Bostock,³ studying his own cases and those of Bright, had arrived at the main truths known today: albuminuria occurs in many circumstances, often "of a trifling nature"; the protein in the urine "possesses every property of that in the blood", the specific gravity of urine from cases of chronic proteinuria is "less than that of the urine in the healthy condition of the system"; "the serum generally in these cases contains less albumin than in health", and "the blood exhibits a very great deficiency of albumin at the same time that we observe the mode by which it passes off from the system by means of the kidney."

The large, greasy yellow kidney found in many cases of Bright's disease, with edema had tubular changes characterized by desquamation, regeneration with mitosis and large amounts of lipid in the cells of the tubules. The changes seem not unlike those in the heart and brain injured by anemia, or in the liver injured by toxins or anoxia. Pathologists were impressed by the severity and constancy of the tubular changes, which they regarded as probably toxic in origin. They even suggested that proteinuria might be due to tubular injury or be produced by tubule cells, as mucus is thrown off by injured cells in the nasopharynx, bronchus or colon. Modern methods such as ultracentrifugation and electrophoresis,^{4, 5} and also specific biologic tests show that the albumin and globulin, which are always found together in proteinuria, are identical in their properties with molecules of protein in the plasma and are not to any appreciable degree derived from the tissues. Studies of fishes with aglomerular kidneys and of others with glomeruli have shown that without glomeruli

^{*}Evans Lecture delivered at the Evans Memorial Auditorium Boston March 27, 1942.

[†]Professor of pathology, Cornell University Medical College.

there can be no proteinuria,⁶ and protein can easily be demonstrated in the fluid about glomeruli in cases of proteinuria.⁷ Finally, staining methods developed at the Mallory Institute of Pathology, of the Boston City Hospital, have made it possible to show that demonstrable glomerular lesions occur in almost all cases of chronic albuminuria.^{8, 9} The problem of proteinuria therefore concerns, primarily, altered permeability in the glomerulus and, secondarily, the effects of this leakage.

Since much information is at hand on the functions of the kidney and on glycosuria and hemoglobinuria, a review of these facts may be useful. By measurement of the ratio of the amount of substance eliminated in one hour's urine to the amount of 1 cc. of plasma (Addis ratio, renal clearance), much has been learned about human renal function. Diodrast clearances are very high, for the tubules and glomeruli eliminate over 90 per cent of the substance as it passes from renal artery to renal vein; this gives a measure of renal blood flow—about 1500 liters a day for a man of normal size. Inulin and sucrose seem only to escape in the glomerular filtrate and to be but little reabsorbed by the tubules; clearance of inulin gives a measure of glomerular filtrate—about 180 liters a day for a man.¹⁰ Richards¹¹ and his co-workers have analyzed glomerular filtrates from mammals and amphibia, finding the glucose, as well as the chloride and urea, similar to that in the blood, whereas protein, if present at all, is only in minute traces, less than 30 mg. per 100 cc. All the glucose is reabsorbed so long as the plasma level is below 180 mg. per 100 cc., and the reabsorption occurs in the proximal convoluted tubules.¹² Above that threshold, glucose appears in the urine, and above 250 mg. per 100 cc., practically the entire excess escapes in the urine, whereas glycogen appears in the tubule cells in demonstrable masses.

Since hemoglobin has 97 per cent the molecular weight of serum albumin and is tagged with a prosthetic group that makes it easy to study, the investigator of albuminuria is naturally interested in the precise studies of Whipple and his co-workers.¹³⁻¹⁷ Unlike Diodrast and neutral red, but like glucose, hemoglobin escapes only through the glomeruli; it is not taken from the blood and excreted by the tubule cells. Animals with no albuminuria show hemoglobinuria only when the plasma level exceeds 100 mg. per 100 cc. However, after prolonged hemoglobinuria, this threshold drops about 60 per cent. The actual leakage through the glomerulus represents only 2.5 to 3.0 per cent of the hemoglobin present in the plasma "cleared" of inulin in the same period. When the blood level is over 100 mg. per 100 cc., hemoglobin and hemosiderin appear in the cells of the proximal convoluted tubule and even farther along

in the nephron. Thus, reabsorption, threshold, and tubular storage and transformation occur with this protein, as they do with the carbohydrate dextrose.

Dawson,¹⁸ Hayman and Richards¹⁹ and Gérard,²⁰ with ingenious technics, introduced colloidal and particulate matter into the proximal end of the proximal convoluted tubule. They found these substances accumulated in visible masses in the cells of the tubules, proving that reabsorption and alteration in dispersion could occur with other substances than glucose and hemoglobin.

In our laboratory, Dr. E. Canat has recently performed some very instructive experiments using trypan blue and T 1824 (Evans's blue), both of which are adsorbed onto albumin, the Evans's blue very strongly. When 5 mg. of the latter dye is injected intraperitoneally in normal rats, no dye appears in the urine, and the proximal convoluted tubules show none after six hours and only very faint staining even after twenty-four hours. The dye is in small vacuoles, barely visible in unstained frozen sections and invisible if the ordinary eosin staining has been used. However, if rats with severe proteinuria (100 to 400 mg. a day) are given similar injections, the urine becomes intensely blue. As much as 0.7 mg. of dye may be excreted the first day, varying with the severity of the proteinuria—roughly 1 mg. of dye per 500 mg. of protein in the urine. But the tubules in the animal's kidney (only a small stump of one kidney remains in the experimental rat) show large, intensely blue granules of dye, and large numbers of such granules may be seen within six hours. The proximal convoluted tubule contains the most dye when the loss in the urine is most intense, but even when no dye escapes in the urine small amounts gradually appear in the tubules. This is interpreted to mean that small amounts of serum protein, with adsorbed dye, are constantly escaping into the glomerular filtrate and being reabsorbed by the tubules. The dye is concentrated in vacuoles after being split off from the protein, and faintly visible amounts occur in the normal animal after many hours. When proteinuria is present, large amounts of dyed protein leak out of the glomeruli, the tubular cells reabsorb large amounts but much escapes in the urine, large granules of dye, split off the protein and concentrated by the tubule cell, become visible in the cytoplasm in a few hours. The analogy with hemoglobin and with glucose is very close, for with these substances what accumulates in the tubules is a polymer or a split product of what was present in excess in the glomerular filtrate. The tubule not only reabsorbs but also "works over" these substances.

With Drs. Canat and L. G. Woolley, I have used Winton's technic (perfusion of kidneys with ice-cold serum) to obtain large quantities of glomerular filtrate. That the glomerular membrane is not damaged in successful experiments can be verified by the observation that hemoglobin added to the perfusate appears in concentrations only 2.5 to 3.0 per cent as great in the glomerular filtrate. In rabbits, the protein content of glomerular filtrate, obtained in volumes as high as 3 cc. a minute, when the tubules are paralyzed by cold, varies from 15 to 22 mg. per 100 cc. The glomerular filtrate thus obtained is water-clear with no tinge of yellow; it is, as Bickford and Winton²¹ showed, a pure ultrafiltrate with the glucose and chloride content of the plasma, and its protein content is about that of spinal fluid. Thus, the dye experiments receive confirmation regarding the probable presence of protein in the filtrate. It is hoped that this technic, applied to kidneys of animals with proteinuria and previously tested with hemoglobin, can give some information of the threshold level at which proteinuria occurs with a rise in protein content of glomerular filtrate.

It is well known that in the intense tubular damage due to severe hemoglobinuria or Bence-Jones proteinuria or with the crush syndrome (myoglobinuria), little or no fat appears in the tubules. In these cases, plasma lipids are normally low. In cases of Bright's disease with edema, with much fat in the tubules, plasma lipids are high, and this lipid is colloidal and often behaves as though adsorbed to globulin. The lipoid is high when the albumin is low, suggesting that when the body can no longer supply colloidal protein to maintain oncotic pressure of the blood, it begins to mobilize colloidal fats. In any event, the blood is presumably the source of the fat that appears in the tubule cells, as it is of the iron in hemoglobinuria, the glycogen in diabetes and the Evans's blue in rats with severe proteinuria. Degenerative tubular changes, as Ekehorn⁷ and Govaerts^{22, 23} suggested, are not the cause but the result of fat and protein accumulation in the tubules. With proteinuria, the cortex of the kidney is swollen, hyaline and granular masses occur in the tubules, and desquamation (up to 100,000,000 epithelial cells a day in the sediment) follows this over-engorgement with reabsorbed materials. Such desquamation is easily repaired, as evidenced by the mitoses seen in these cases, and the tubular functions are scarcely altered. Cats normally have far more fat²⁴ in their tubules than is seen in the severest human nephrosis, and of course they too have excellent tubular function. Until the tubules are severely altered, as in anuric cases of hemoglobin or myoglobinemia,²⁵ the degenerative

change secondary to reabsorption leaves renal function almost intact. It is not impossible, however, that chronic proteinuria lowers the threshold at which protein leaks out of the body, and severe tubular changes may diminish capacity to reabsorb protein. In any event, the chief and the primary change is the rise in protein in the glomerular filtrate to levels at which tubular reabsorption no longer keeps pace with the supply. If the normal man has a threshold for spilling protein at 40 mg. per 100 cc., and normally has only 15 mg. per 100 cc. in the filtrate, he would have, in his 180 liters of filtrate a day, 27 gm. of protein, with none in the urine. At 41 mg., he would have 74 gm. in the filtrate and 2 gm. in the urine; if his threshold fell to 30 mg., with 41 in the filtrate, he would have 74 gm. in the filtrate and 20 gm. in the urine. These hypothetical figures give an idea of the way in which a slight rise in protein (or glucose or hemoglobin) in the filtrate can cause a huge increase in the urinary loss.

Proteinuria offers problems of diagnosis in medicine, pediatrics, surgery and obstetrics. Many types of investigation may be required to elucidate the cause in some cases, but no technic is more frequently of value than the quantitative study of the rate of loss of protein, cells and casts in the urine. Richard Bright set a bad example by sending his patients' blood and urine to Bostock, since in any field real skill is achieved only by those who thoroughly master and constantly employ the special technic necessary for study. It is as essential for the renal specialist to look at sediments obtained under standard conditions as for the heart specialist to do his own auscultation or the dermatologist to look at the entire skin surface.

There is evidence from the work in many laboratories on which to base an understanding of proteinuria and associated renal changes. This basis fits in with the knowledge of glycosuria and hemoglobinuria. But it leaves the central problem—the nature and cause of altered glomerular permeability—unanswered. More careful and constant scrutiny of patients and more ingenious and well-planned experiments will undoubtedly unravel much of this fundamental mystery.

MEDICAL PROGRESS

REGIONAL ANESTHESIA

MANSON BROWN, M.D.,* AND MORRIS J. NICHOLSON, M.D.†

BOSTON

THE current progress of regional anesthesia is characterized by an interest in its military application, by increasing confidence in spinal and fractional spinal anesthesia, and by widening the use of block technics in the therapeutic field. Studies of anoxia, respiratory drive and vascular collapse have helped to rationalize the conduct of both spinal and general anesthesia.

Lahey¹ has pointed out that trained anesthetists in military service will contribute definitely to a lowered surgical mortality rate. In their hands, local anesthetics may be differentiated on the basis of effect on wound healing,^{2,3} fractures may be remobilized,⁴ and the use of spinal anesthesia will develop both in surgery and in the treatment of shock from injuries to the lower extremities.⁵

NEW AGENTS

Of the newer drugs available for regional anesthesia, monacaine hydrochloride,⁶ an isomer of procaine, holds some promise. Somewhat more toxic than procaine, it is more stable to room temperature and light and equally stable to sterilization, has a distinctly greater affinity for motor nerves, and is clinically reported to afford more lasting anesthesia.⁷

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress Annual*, Vol III, 1942 (Springfield, Illinois: Charles C Thomas Company, 1942 \$5 00)

*Formerly, fellow in Department of Anesthesia, Lahey Clinic, now, First Lieutenant, M C, A U S.

†Member of the Department of Anesthesia, Lahey Clinic, anesthetist, New England Deaconess Hospital, associate anesthetist, New England Baptist Hospital.

Alkaline salts of procaine borate⁸ are less irritating than the commonly used hydrochloride, but deteriorate rapidly at room conditions. Potassium salts of procaine afford more lasting anesthesia, but are immoderately irritating.

Laboratory studies have suggested that Intracain⁹ might afford anesthesia twice as lasting as equivalent doses of procaine, but clinical trials have not confirmed this.

A group of piperidine derivatives¹⁰ has been studied and listed as PT-1, PT-4, PT-6, PT-14 and PT-19. Of these, PT-19 appears most promising, providing spinal anesthesia twice as lasting as procaine. In infiltration anesthesia, it is more toxic and less efficient than procaine. Clinical trial has not been reported.

Neothosol in almond oil¹¹ has been used without complication in 427 cases to secure prolonged anesthesia in abdominal wounds by infiltration during surgery. Research work on cats, with placement of this oil in healing wounds, revealed on microscopy little or no resulting reaction.

Isoamyl cupreine¹² (eucupin in oil and in Ringier's solution) has been utilized to infiltrate and to block operative wounds of the upper abdomen. Postoperative vital capacity is increased, and sequent analgesia (sometimes without anesthesia) decreases the patient's discomfort. Laboratory work suggests that accidental intrapleural injection of local agents in oil during nerve-block procedures may have no lasting ill effect.

THERAPEUTIC USES

The medical literature records an increasing use of local anesthesia in therapeutics. The antiseptic agent, *rivanol*,² combined with a local anesthetic, is suggested as an adjunct in the care of contaminated, painful wounds. This suggestion is timely, since local anesthetics derived from *p*-aminobenzoic acid (procaine) are antagonistic to the action of sulfonamide drugs when both are present in infected tissue.³ Local anesthetics in oil for prolonged anesthesia, or repeated paravertebral block of abdominal wounds, may decrease postoperative pulmonary complications. Regulated cell reception of a local agent in a slowly absorbable, non-toxic, gelatinous medium is claimed to have a similar effect.¹³

Local infiltration facilitates early mobilization in the treatment of fractures of nonweight-bearing bones and minor injuries,⁴ for example, those involving the back, shoulder, hand, wrist, ankle and foot.¹⁴ Fractured ribs may require only one or two injections for complete rehabilitation.¹⁵ Asthma and age are particular indications for such care. Anesthetic block is an adjunct to the treatment of fibrositis or bursitis,¹⁶ and offers temporary relief as well as frequently prolonged remission of neuritides, particularly the trigeminal, occipital, cervical, brachial, intercostal or sciatic types.¹⁷ Pain in amputation stumps may be interrupted or ended. Sympathalgia or causalgia of the face, traumatic "hard hand," or hyperhidrosis of the upper extremities may be improved by block of the stellate ganglion.

Articles by Bartlett¹⁸ and Seldon¹⁹ evaluate regional-nerve-block techniques for surgery below the clavicles. Bilateral intercostal block is simple and serves admirably for plastic procedures on the upper abdominal wall, herniorrhaphy and closure of colostomy. Subtotal gastric resection in the patient who is a poor risk may be done readily under field block, with supplementary splanchnic block through the operative incision.^{20, 21} By this method, Finsterer²² reports good anesthesia in 90 per cent of 2442 cases; de Takats²³ reports success in 87 per cent of 1292 operations. General or fractional spinal anesthesia is needed for total gastric resection.

Tuohy,²⁴ of the Mayo Clinic, outlines excellent regional-block techniques for saphenous ligation or femoral herniorrhaphy. He also describes procedures for caudal and transsacral blocks for anoperineal surgery and for work on the lower extremities.

Fetal and maternal risks are at a minimum under various types of caudal or, preferably, infiltration anesthesia.^{25, 26} Results under the latter are con-

sistent; perineal relaxation is notable, facilitating such procedures as low forceps, Scanzoni's maneuver, manual rotation, spontaneous breech and episiotomy. Anesthesia persists for one and a half to two hours.

The paravertebral sympathetic block for thrombophlebitis is an outstanding therapeutic application of regional anesthesia. All patients with superficial thrombophlebitis with pain and edema should have block and conservative measures.^{27, 28} In patients with deep phlebitis without lung infarction, those under forty years of age need sympathetic block and conservative measures. In those from fifty to seventy years of age, 7 per cent suffer pulmonary infarcts, and ligation with block should be done early. In patients over seventy years of age, 20 per cent are likely to have pulmonary infarcts; in this group, ligation is obligatory, and blocks may be palliative.²⁹ Ten cubic centimeters of 1 per cent novocain with epinephrine—1:200,000 at the first, second, third and fourth lumbar vertebrae—will give relief in ten minutes and marked improvement in an hour. Blocks should be repeated one or more times daily until the temperature levels. Lumbar paravertebral block will improve claudication if sympathectomy is indicated.³⁰ If done preoperatively, this procedure prevents ischemic gangrene after surgery on large arteries.³¹

Paravertebral dorsal procaine block eases pain in postoperative upper abdominal wounds and raises the postoperative vital capacity, which is usually between 20 and 40 per cent of normal, to 90 per cent of normal. This permits hyperventilation and cough, with less tendency to atelectasis.³²

Paravertebral alcohol injection may be preceded by diagnostic paravertebral cervicodorsal block for the relief of anginal pain or asthma.³³

X-ray studies of 2 per cent novocain in opaque oil show that in epidural anesthesia in human beings, the onset of anesthesia follows diffusion of the agent out along the nerve roots.³⁴ This method may be used caudally for sciatica, dorsally for relief of intractable pain in carcinoma, at about the seventh cervical to the second dorsal vertebra for angina or asthma, and at selected levels for thoracic surgery. In the thoracic field, spinal anesthesia is less desirable than epidural anesthesia, which does not diffuse to bulbar centers; the effect can be limited to a few spinal segments, the blood pressure fall, nausea and vomiting are less, and "puncture headache" is decreased.³⁵ A mixture of pontocaine and procaine may afford anesthesia for two hours or longer.³⁶ Some danger results if an accidental puncture of the dura is made, in view of the large amounts of agent commonly used (20 to 50 cc. of 2 per cent novocain).³⁷

SPINAL ANESTHESIA

Of the agents available for spinal anesthesia, procaine continues to be used most commonly; however, there is a tendency toward the use of solutions weighted with 6 to 10 per cent glucose to facilitate ready gravitation of the agent to desired sensory spinal levels.³⁸ In Britain, Percaine (nupercaine),³⁹ 1:200 with 6 per cent glucose, as well as pontocaine-glucose, is utilized; in this country, pontocaine hydrochloride, 1 per cent in 10 per cent glucose, is gaining popularity and has been used at the Lahey Clinic in about 8000 cases without a serious complication referable to the agent.

A significant contribution to subdiaphragmatic surgery during the last decade is the development of fractional (continuous) spinal anesthesia. This type, maintained with rubber tubing and an indwelling soft German-silver spinal needle, has now been used in a sufficient number of cases to permit evaluation.⁴⁰⁻⁴² It is particularly adapted to prolonged surgery in patients who are poor risks, in whom relaxation is desirable. The incidence of complications referable to the anesthesia is not greater than with any other comparable method.

Spinal anesthesia has been carried to cervical levels with some success, permitting such operations as mastoidectomy. On physiologic bases, this cannot be approved for it brings the agent perilously close to medullary centers, and depends on the selective paralysis of the sensory to the motor (phrenic) nerves.⁴³

Bourne,⁴⁴ who has modified the Etherington-Wilson technic for nupercaine to secure satisfactory spinal anesthesia for thoracic surgery, believes that with the use of this agent breathing is quieter, paradoxical breathing is decreased and secretions are less, and that the prolonged post-operative anesthesia aids convalescence. In these cases, intercostal or epidural block seems a more rational substitute for general anesthesia. Intratracheal cyclopropane or ether may be wholly preferable.

In the past, the fall in blood pressure experienced with spinal anesthesia was a barrier to its use for cesarean section. However, Heard⁴⁵ regards this disadvantage of spinal anesthesia as slight when the depressing effect of ether on the mother and fetus is considered. This bad effect of ether reaches its peak in abnormal fetuses or in heavy sedation of the mother. Circulatory, respiratory and genitourinary complications are reduced when spinal anesthesia is used, and the baby is not narcotized.⁴⁶

Hunt and Lundy⁴⁷ favor local or field block for cesarean section. To this technic, they have added

the intravenous administration of Pentothal Sodium when the uterus is opened because at that point some of their patients complained of distress. Oxygen or 50 per cent nitrous oxide and oxygen may be given for a few minutes if much Pentothal seems indicated.

CAUDAL ANESTHESIA . . .

Caudal anesthesia may also be utilized in parturition. Lahmann and Mietus⁴⁸ report 400 cases without incident, except a 2.5 per cent failure to produce anesthesia. Perineal relaxation occurs, contractions are painless, the uncontrolled "push urge" is diminished, separation and involution are normal, and the mother is rested. Continuous caudal anesthesia is also being used in obstetrics.⁴⁹

SUPPLEMENTARY ANESTHESIA

Premedication should be considered supplementary anesthesia, and is a vital factor in spinal anesthesia of any type. Pantopon in adequate doses, used instead of morphine, tends to decrease the incidence of nausea and vomiting.⁵⁰ Scopolamine is preferable to atropine, creating twice the drying effect and twice the psychic depression. The depressant effect of morphine, too, is more satisfactorily counteracted.⁵¹ When the drug is combined with Pantopon and a barbiturate if indicated, the exciting effect of scopolamine largely disappears.

Extensive surgery under spinal anesthesia may necessitate additional supplementary anesthesia, particularly if mesenteric traction initiates nausea and vomiting. The high concentration of oxygen that may be administered with cyclopropane is desirable but, in intra-abdominal surgery, may be contraindicated by the use of the cautery. In these cases, Pentothal Sodium administered by fractional doses into a continuous intravenous-drip apparatus is convenient. However, its depressing effect on the respiratory drive mechanism⁵² makes logical the simultaneous administration of nitrous oxide and oxygen, to prevent the patient from going into central respiratory failure.⁵³

SUPPORTIVE MEASURES

The value of an adequate oxygen supply to patients under prolonged spinal anesthesia with associated low blood pressure cannot be overemphasized. Arterial oxygen saturation, 5 to 45 per cent below normal in the head, can cause cerebral damage and a marked increase in water content (edema) of cerebral tissue.⁵⁴ This depression, added to the accepted histotoxic depression of Pentothal or preoperative barbiturates, helps to explain many of the accidents that have retarded the progress of spinal anesthesia.⁵⁵

The dangers of anoxia are inseparable from the problems of shock. Certain tests may detect shock during its earlier stages when significant changes are noted in the hematocrit, the specific gravities of the plasma and whole blood, and the plasma protein level.⁵⁶ The primary fall in blood pressure in spinal anesthesia probably depends on peripheral vasomotor paralysis. Other mechanisms accounting for the fall in blood pressure beyond the level caused by peripheral vasodilatation, suggested by Nowak and Downing,⁵⁷ are the central effects of vasomotor change and anoxia, in addition to medullary paralysis caused by direct extension and vascular absorption of the drug. When these tests or clinical observation indicate that shock is developing, electrolytes may be restored with physiologic saline, capillary tone with vasopressors and cortical extract, and the circulation sustained with blood or plasma.^{58, 59} Meanwhile, oxygen should be available, flowing in concentrations of about 60 to 75 per cent. Carbon dioxide should not be administered to spinally anesthetized animals or patients, since it lowers their blood pressure,⁶⁰ has little or no effect on respiration and contributes to already present anoxia.⁶¹

To combat the fall of blood pressure common with spinal anesthesia, ephedrine has proved to be the vasopressor of choice. As a working hypothesis, one may assume that spinal anesthesia blocks the sympathetics to the adrenals and lowers the epinephrine available. Then, if ephedrine is administered, it blocks amine oxidase, the epinephrine neutralizer, freeing "frozen" epinephrine. If ephedrine and fluids do not raise blood pressure and speed circulation, a small intravenous dose of epinephrine helps the depleted stores.⁶² A mixture of Pitressin and ephedrine elicits a more rapid and prolonged effect than ephedrine alone.⁶³ Too liberal administration of these pressor drugs may be somewhat dangerous in patients with arteriosclerosis or coronary disease. Epinephrine alone is efficacious, but its effect curve is too short and peaked.⁶⁴

An intermediate substitute for epinephrine is Synephrin tartrate.⁶⁵ A dose of 400 mg. secures a marked systolic rise, a slight diastolic rise and a slight fall in pulse rate. The onset is rapid, and the duration is over one hour.

Gaining favor is the related Neosynephrin, longer acting than ephedrine, and having less pressor and cardioirritant effect and more sympathetic side-effects.⁶⁶ The associated apnea sometimes observed is probably a carotid and aortic-body response to rapid elevation of blood pressure. The threshold doses are 2 mg. subcutaneously and 0.4 mg. intravenously; the average effective doses are 5 mg. subcutaneously and 0.8 mg. intravenously.

Overdosage creates cardiac irregularity and electrocardiographic variations.⁶⁷

Adrenocortical hormone (cortin) and desoxycorticosterone have been suggested as aids in the maintenance of blood pressure and in the treatment of shock. Desoxycorticosterone has no established value here. However, cortin has at least three uses: it protects against traumatic and adrenalectomy shock⁶⁸; under anoxic conditions, it is needed to mobilize catabolic protein and spare liver glycogen⁶⁹; and in the treatment of shock, it has a definite use in mobilization of fluids, particularly parenteral saline and plasma.⁷⁰

COMPLICATIONS

The complications arising under regional anesthesia are so varied as to prohibit an integrated discussion, but certain facts stand forth. Lyford⁷¹ reports that patients with normal respiratory systems before surgery have postoperative respiratory infections in about 6 per cent of cases; there is no relation to type of anesthesia. He states that patients with low-grade respiratory infection before surgery will have acute postoperative episodes two and a half times more frequently with spinal anesthesia than with inhalation anesthesia (spinal 39.5 per cent; ether 13.5 per cent; cyclopropane 17.5 per cent).⁷² These figures are not in accord with the very excellent work of King⁷³ at the Massachusetts General Hospital.

Postoperative atelectasis—much of the "ether pneumonia" of other days—has yielded well to catheter aspiration with conservative hyperventilation, together with limitation of sedatives. If this fails, therapeutic bronchoscopy is indicated, even in very sick patients, for pneumonia in a collapsed lung is far more inimical than bronchoscopy performed by fairly skilled persons.^{74, 75}

The prevention of atelectasis may be possible. Capelle⁷⁶ observed that the usual postoperative vital capacities of 20 to 40 per cent of normal were increased to 90 per cent of normal by continuous local anesthesia of abdominal wounds. Gius,³² impressed with Capelle's work, tried paravertebral intercostal block for atelectasis occurring after appendectomy in children, with notable success. Subsequent studies of vital capacities after abdominal surgery indicate that respiratory excursion, cough and movement are markedly facilitated by prolonged or repeated block anesthesia. Infiltrating such a wound at the end of an operation sometimes affords later analgesia without pinprick anesthesia.⁷² Starr and Gilman⁷⁷ report 23 per cent increase in postoperative vital capacity with blockage of the sixth to the tenth dorsal nerve inclusive.

The selection of cases (preoperative respiratory conditions) and of operations (nephrectomy and

cholecystectomy) for therapeutic intercostal block may markedly decrease the incidence of atelectasis. Few patients will object, for marked comfort is afforded.

The hypnotic drugs, such as Pentothal and Evipal, may create surgical or postoperative depression. At a deep anesthetic level (stage III, plane II), the cerebral respiratory centers may cease to function, and respiration becomes dependent on anoxic stimulation of the carotid sinus and aortic body. Carbon dioxide may pile up in the circulation until it actually interferes with oxygen transfer to tissues.⁶¹ At this point, a sudden supply of oxygen by mask may throw a patient into irreversible apnea.⁵² Such hypoxia is not well tolerated by patients under spinal anesthesia; therefore, hypnotics as supplemental anesthetics must be handled carefully. Postoperative hypnotic depression may be counteracted by benzedrine.⁷⁸ As yet, no relation between hypnotics and the toxicity of sulfonamides has been established.⁷⁹

Convulsions after bronchoscopy under topical pontocaine hydrochloride have been controlled by three 2-cc. doses of Dial.⁸⁰ Research suggests that in such cases calcium levulinate, calcium gluconate and calcium chloride are protective, in that order.⁸¹ Calcium chloride and Salyrgan protect against procaine convulsions, but only if injected with the anesthetic.⁸² Barbiturates given preoperatively protect, but increase the danger if injected with the anesthetic. Barbiturates used to excess for the control of cocaine convulsions cannot be counteracted as usual with Metrazol or picrotoxin; patients may have convulsions without awaking.⁸³

Further complications described in the literature are abducens paralysis, meningitis,⁸⁴ ventricular fibrillation, urinary retention and cauda-equina injury. Urinary retention, occurring in about 3 per cent of cases, usually responds to constant or tidal drainage with sulfonamide irrigations. Resection of a portion of the bladder sphincter has cured a refractory case.⁸⁵ Reported cauda-equina injury was seen in several patients given Spinocaine. Ferguson and Watkins⁸⁶ reported 14 such cases among seventeen hundred spinal anesthetics under durocaine, a procaine-gliadin-glycerine solution in 15 per cent ethyl alcohol.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 28431

PRESENTATION OF CASE

First admission. A fifty-eight-year-old man was admitted to the hospital because of a feeling of substernal oppression.

One year prior to admission the patient began to suffer with attacks of substernal oppression and chest tightness after exertion, without severe pain. These attacks were reduced in severity by rest and lessened activity. During the week prior to admission he suffered with almost daily attacks of "fluttering and bumping of the heart," each lasting about five minutes. During the attacks he had a feeling of impending danger; however, no remarkable pain developed.

The family history was noncontributory. Twenty-nine years previously the patient had had malaria, but since then he had had no chills. He did not recall having had any other tropical diseases.

Physical examination revealed a well-developed and well-nourished man in no apparent distress. The chest was of an emphysematous type but was otherwise normal. The heart when outlined by percussion was questionably slightly enlarged. The sounds were distant and faint. A blowing systolic murmur was audible at the apex. The abdominal examination was unremarkable, and no masses were felt.

The blood pressure was 120 systolic, 80 diastolic. The temperature was 99°F., the pulse 90, and the respirations 20. Several hours after admission the pulse was found to be 49, and during hospitalization it ranged between 50 and 60.

Examination of the blood revealed a red-cell count of 4,730,000 with a hemoglobin of 85 per cent, and a white-cell count of 10,800 with 68 per cent polymorphonuclears, 26 per cent lymphocytes and 6 per cent monocytes. The urine was normal except for a rare red cell and 2 white cells per high-power field in the sediment. The blood Hinton test was negative. The blood nonprotein nitrogen was 23 mg. per 100 cc. The sedimentation rate was reported 1 mm. in fifteen minutes, 4 mm. in thirty minutes, 6 mm. in forty-five minutes and 8 mm. in sixty minutes. An electrocardiogram demonstrated a normal sinus rhythm of 60 per minute. The P-R interval was 0.19 second; T₃ was inverted, and there was a slight amount of

left-axis deviation. The patient was discharged after three days and advised to take Nembutal at bedtime and 3 gr. of quinidine sulfate fifteen minutes before each meal.

Second admission (nine months later). The patient was readmitted because of a recurring fever of about 101°F., weakness and night sweats. These symptoms developed three months after discharge and seemed similar to the fever and chills with which he had suffered in the attack of malaria. A typical episode began at night with chills and trembling, followed by fever of 103°F., vomiting and sweating, which gradually decreased during the night leaving him weak but quite all right during the next day. Six weeks before entry he again began to have night sweats and evening fever, and these symptoms continued intermittently to the day of admission, being slightly mitigated by sulfadiazine administered by his local physician. Three weeks before entry his face became swollen and pink, and this skin flush gradually extended over the chest and abdomen and lasted several hours.

Physical examination was similar to that noted above except that the patient was obviously feverish. The soft systolic murmur was audible over the entire precordium, but best heard at the apex, and was transmitted into the left axilla.

The blood pressure was 110 systolic, 60 diastolic. The temperature was 101°F., the pulse 85, and the respirations 24.

Examination of the blood revealed a hemoglobin of 16.1 gm. and a white-cell count of 8000 with 75 per cent polymorphonuclears, 17 per cent lymphocytes, 7 per cent monocytes and 1 per cent blasts. The red blood cells appeared fairly normal; the platelets were slightly increased. No malaria parasites were seen. The urine examination was similar to that of the previous admission. A stool examination was negative for mucus and blood. Repeated examinations of the blood were not remarkably different, and no malaria parasites were found. Agglutination tests for undulant fever were negative, and the Widal test was negative. Repeated blood cultures revealed no growth.

An x-ray film of the chest demonstrated a small, rather sharply defined area of density in the right second interspace. There were areas of calcification in the right lower lung field, and linear scars in the left costophrenic angle. The heart was prominent in the region of the left ventricle. The aorta was tortuous. An electrocardiogram was similar to that taken during the previous admission.

During the nine days in the hospital, daily periods of fever up to 103°F. and sweating occurred in the evening, in spite of a brief course

of quinine sulfate. He was discharged with plans for readmission a week later. His fever had subsided somewhat.

Third admission (two weeks later). Since discharge he had had a gradual return of pyrexia, although for the first week at home his temperature was subnormal.

The physical examination had not changed except that the patient was definitely sicker.

The temperature was 101.4°F., the pulse 89, and the respirations 20.

The hemoglobin level was 10.3 gm., and the white-cell count 9200 with 64 per cent polymorphonuclears, 17 per cent lymphocytes and 19 per cent monocytes. No malaria parasites were seen in the blood smear. The urine examination was unchanged except for a + test for albumin. An electrocardiogram did not demonstrate any remarkable change. An x-ray film of the chest showed some hazy density extending upward and posteriorly from the right hilus, apparently in the apex of the right lower lobe.

The patient was discharged after six days without much improvement.

Final admission (two weeks later). Since discharge, he had had a subnormal temperature for one week and then it gradually rose from an evening peak of 99°F. on the first day of the week to 104°F. on admission, with profuse night sweats and daily remissions. He had been taking 40 to 80 gr. of aspirin each day and had recently developed some deafness and ringing in the ears. Three or four days before entry he noted the onset of attacks of rapid pulse, which often rose from 78 to more than 150. These changes occurred suddenly, lasted a few minutes and stopped suddenly. He had had twenty to twenty-five attacks during the four days prior to admission. They were accompanied by a burning headache and perspiration. All these symptoms ceased with cessation of the rapid pulse rate. There was no dyspnea or precordial distress with the attacks.

Physical examination revealed a flushed, apprehensive man with a hot, dry skin, who looked chronically, but not acutely, ill. The examination of the lungs was normal, except for equivocal dullness at both bases posteriorly and a suggestion of bronchovesicular breathing in these areas. A few fine rales were audible at both bases. The heart was markedly enlarged to the left in the anterior axillary line, and the apex impulse was felt in the left fourth interspace in the anterior axillary line. There was a moderately loud blowing systolic murmur over the entire precordium which was best heard at the apex and was transmitted to the left axilla. A somewhat rasping but soft systolic murmur was audible at the base and in the neck vessels. Along the left border of

the sternum there was a midsystolic scratching sound, which seemed more like a precordial rub than transmission of a systolic murmur.

The blood pressure was 134 systolic, 74 diastolic. The temperature was 104°F., the pulse 90, and the respirations 32.

Examination of the blood revealed a hemoglobin of 9.7 gm. and a white-cell count of 5600 with 86 per cent polymorphonuclears, 10 per cent lymphocytes, 2 per cent monocytes and 2 per cent myeloblasts. The urine was unchanged, as was an x-ray film of the chest. In the flat plate of the abdomen the kidney shadows were obscured by overlying bowel but were not grossly abnormal. There was a small area of density overlying the right side of the sacrum. Further blood cultures revealed either no growth or obvious contaminants. The urine culture was negative. A stool examination was negative for blood, mucus, amebae and amebic cysts. An intravenous pyelogram was negative. A cephalin flocculation test was +++ at 24° C. and ++++ at 48° C., but in the liver-function test there was less than 5 per cent of the dye in the serum. One month after admission, tiny lymph nodes about 5 mm. in diameter, were felt in the neck on each side.

Since no diagnosis was established, the patient was empirically treated with a course of sulfadiazine by mouth, totaling 69 gm. in seventeen days. The blood level established apparently did not exceed 5.9 mg. per 100 cc. There was only a moderate reduction in the temperature during the course of sulfadiazine, and the patient was not remarkably improved. His fever continued to spike to 103 or 104°F. almost every day. Short courses of quinine sulfate and Atabrine were administered without obvious improvement. In spite of supportive and symptomatic treatment, the patient gradually became weaker. In the last week before death, three small lymph nodes became palpable for the first time in the groins, and the patient gradually became moderately jaundiced. Symptoms of fever and chills continued, and the patient died three months after admission.

DIFFERENTIAL DIAGNOSIS

DR. FRANCIS R. DIEUAIDE: In reading through the abstract, we note that the first complaints were those of anginoid attacks with runs of premature beats, that is, short attacks of paroxysmal tachycardia or possibly, though less likely, paroxysmal auricular fibrillation. These were repeated during the fourth admission. The mid-diastolic scratching sound along the left border of the sternum leads me to believe that the patient had a mild pericarditis at the time of the fourth admis-

sion. The blood pressure showed changes up and down, which were not, however, very great.

The blood changes include the finding of 19 per cent monocytes and 1 per cent myeloblasts on different occasions. It is not safe to attribute great importance to these. By the time of the last admission there was moderately severe anemia. The whole course of the patient, if we consider the beginning to be when he first had substernal discomfort, took about two years. The chills and fever lasted about ten months. These recurrent attacks of fever are very striking and must contain the central clue to the diagnosis. Apart from them, the findings point in three directions.

Certain findings relate to the heart. We know that the patient had substernal discomfort. He had paroxysmal attacks of tachycardia, with some variation in blood pressure, and developed marked enlargement of the heart to the left, with a loud systolic murmur. He apparently never developed congestive failure, had no sign of valvular disease and, during observation, had no hypertension. He probably had a short episode of acute pericarditis during the last admission. There is no reason to think he had a huge pericardial effusion as a possible explanation of the apparent enlargement of the heart.

Another direction in which our attention is drawn is the liver, since we are told that the patient had jaundice.

The third direction we must consider is suggested by the lymph glands in the neck and in the groin, which were small and apparently did not attract much attention. There were also some findings in the chest.

May we see the chest films, please?

DR. GEORGE W. HOLMES: The shadows spoken of in the chest are these small spots of calcification. I should not say that they had any particular bearing on this patient's story.

There is a moderate amount of tortuosity of the aorta, and the heart seems to extend a little farther to the left than usual, but in view of these other things I doubt if it is actually enlarged. The left ventricle is perhaps a bit prominent. The other things that were mentioned I think are of no importance. These lines are probably blood vessels; there is nothing characteristic about them.

DR. DIEUAIDE: Do you think anything of that shadow at the right hilus?

DR. HOLMES: No; one might say the pulmonary vessels are a little prominent. I do not believe that would be of any aid in the diagnosis or that one was justified in saying it was definitely abnormal.

DR. DIEUAIDE: I am very humble about this, but is that not a well-defined outline at the hilus—more so than usual?

DR. HOLMES: I do not believe so. I should not call it abnormal, much as I should like to agree with you. There is one strange thing about this. At one time his heart was said to have been enormously enlarged. I do not see any evidence of it in any of the films. If he did have enlargement, it apparently disappeared.

One would like to try to find out something about the size of the liver though these films were not taken for that purpose. It is not enlarged; if anything, it is small. Also you can see the outline of the spleen, and that does not seem enlarged. The kidney shadows are large as we see them on the film but no larger than a heavy man should have. They are magnified a good deal.

I am afraid most of my evidence is negative.

DR. DIEUAIDE: If we depart for a moment from this point and think about the febrile course, which is the most striking aspect of the case, we must run over a number of possibilities. In the first place there are many varieties of low-grade septicemia, including bacterial endocarditis, brucellosis and many other infections. This patient had a normal white-cell count, which is against many of these infections, but is not exclusive. He had no enlargement of the spleen, so far as we know, and no embolic phenomena (petechiae, subcutaneous nodules, nephritis, and cerebral or pulmonary embolism). He had no valvular disease of the heart, which puts out bacterial endocarditis. He had many negative blood cultures, which in the end one has to take as being against septicemia.

One should always consider tuberculosis. This man was fifty-eight years old; it is the fashion to think that people as old as that do not get tuberculosis and die of it, but this is a mistake—they do. On the other hand, in ten months, tuberculosis should declare itself in the chest, abdomen or meninges, unless one is dealing with some peculiar localization, such as the adrenal glands, of which there is no indication. Tuberculosis is not out of the question, but I do not believe it is the diagnosis.

Typhoid fever is always mentioned in these cases. Again, in ten months it should be picked up, and I think we can throw out the possibility.

Is this malaria after twenty-nine years, without any remissions after quinine, without any enlargement of the spleen and with death? No, I do not think the patient had malaria.

A new growth, such as lymphoma, has to be one of the possibilities that we think of seriously. Such a patient would be studied thoroughly for some localization of the tumor, and I assume that this was done. Could these little lymph nodes be the only signs of new growth? Could this shadow

in the chest be a mass of lymph nodes and be more significant than hilar vascular changes? In this large group of possibilities cannot be left out.

Next, we must consider hepatic disease. The patient undoubtedly had some form of liver disturbance, since he had progressive jaundice. The abstract gives only the results of liver function tests and does not mention palpability of the organ. Perhaps we may assume that it was not palpable. The flocculation test was positive, but the bromsulfalein test gave normal results. It might be of interest to know whether there was a long interval between the bromsulfalein test and death.

DR TRACY B. MALLORY: There was a three month interval.

DR DIEUVIDE: In other words, the bromsulfalein test was done at the beginning of the third admission, and therefore it does not do what we should like it to do. If the patient had diffuse liver disease at the time of death, I am sure that the bromsulfalein test would not have been normal at the end. With serious disease of the liver as the fundamental cause of death, we should expect a declaration of the disease in a well observed patient in the form of jaundice, ascites, liver enlargement, pain about the liver and evidence of hepatic insufficiency. Of these only jaundice appears. I do not believe that hepatic disease was the cause of death.

Phlebitis might be mentioned, but there is no lead to that—no localizing signs and no evidence of embolism.

Then, there are certain obscure diseases that have to be brought up. I suppose there are many others, but there are three which especially come to mind. disseminated lupus, sarcoid and periarteritis nodosa. So far as disseminated lupus and sarcoid are concerned, we have not the vaguest clinical suggestion that either of these conditions would have been found post mortem. Periarteritis nodosa could be the diagnosis, although there is a question whether patients have been seen with such fever as this. I hope someone else will speak about this point before we know the diagnosis. So far as I know, the febrile episodes are out of line with this possibility, but many of the other findings are not. In the first place, some of the cardiac events would fit in—the anginoid syndrome, with the substernal oppression, the variation in the blood pressure and even cardiac enlargement and pericarditis; the age and duration of the disease are compatible. The patient did not have the outstanding characteristic features of periarteritis, such as leukocytosis, eosinophilia, abdominal pain, nodules, enlargement of the

spleen and so forth. However, all these findings are seen in only a very moderate percentage of patients with periarteritis nodosa.

As Dr. Mallory anticipated, I am unable to make a definite diagnosis. I am going to make periarteritis nodosa my first choice and put down neoplasm, perhaps lymphoma, in the next line.

CLINICAL DIAGNOSIS

Hodgkin's disease?

DR DIEUVIDE'S DIAGNOSIS

Periarteritis nodosa?

New growth (possibly lymphoma)?

ANATOMICAL DIAGNOSES

Malignant lymphoma, Hodgkin's sarcoma type, involving lymph nodes, spleen and bone marrow.

Icterus

Central necrosis of liver.

Atherosclerosis moderate aortic, coronary and pulmonary.

Emphysema, moderate.

Cholelithiasis.

PATHOLOGICAL DISCUSSION

DR. MALLORY: This was obviously a most obscure case. At autopsy, we found several very slightly enlarged lymph nodes, a perfectly normal liver and a slightly enlarged spleen without any characteristic markings or nodules. It seemed to me impossible to make any diagnosis on the gross findings. When the microscopic sections came through, it was obvious that these not very important looking nodes all showed typical Hodgkin's disease, that there were many scattered Sternberg cells in the unimpressive spleen and that the major Hodgkin's disease was in the bone marrow, which was almost 75 per cent replaced by the disease. The heart was normal in size, and there was only 80 cc. of pericardial fluid. There was nothing to indicate that there had ever been a pericarditis. There was moderate emphysema.

A PHYSICIAN: Was there a mediastinal mass?

DR. MALLORY: There was very slight enlargement of the hilar glands, but no mass.

DR. DIEUVIDE: Did they show Hodgkin's disease?

DR. MALLORY: Yes.

CASE 28432

PRESENTATION OF CASE

A thirty two year old man was referred to the hospital because of fever, chills, diarrhea and jaundice.

Three weeks prior to admission he noticed extreme weakness on arising in the morning. He went to work but was forced to return home in the afternoon because of extreme weakness and fatigue. Because he did not feel up to par, he took a laxative, which produced watery stools for two days. At no time was blood noticed in the stools. He was seen on the following day by his physician, who told him that his temperature was 102°F. He was urged to enter a hospital, but he postponed this for four days, during which period he had several chills and suffered with vague poorly defined abdominal pains largely confined to the epigastrium but not well localized.

On admission to a community hospital he was very dehydrated and prostrated, obviously quite ill. He was treated with sulfathiazole, apparently by mouth and, after 45 gr. of the drug had been given, was found to be jaundiced. For this reason the drug was discontinued. Laboratory studies revealed a red-cell count of 4,200,000 with 80 per cent hemoglobin, and a white-cell count of 6000 with 90 per cent polymorphonuclears. Two blood cultures were reported negative. A test for Weil's disease done at a federal laboratory was reported negative. Repeated Widal tests were negative. The urine was negative except for a rare red blood cell, an occasional granular cast and many bacteria. The stool examination revealed only a ++ guaiac test. The stools did not contain gross blood and were not tarry. The van den Bergh test and icteric index were first reported 10.7 mg. per 100 cc. and 13, respectively, and when repeated several days later, were 5.27 mg., and 6.7. During the two weeks in the hospital he became progressively anemic and the white-cell count rose to 12,000. He became progressively worse, the illness being characterized by weakness, chills and evening temperature elevations to 106.8°F., with a morning temperature of 100°F. At times he complained of a slight pain localized in the upper abdomen. Bowel movements were regular, but the stools seemed to be lighter in color than normal. There were no urinary symptoms. Because no diagnosis could be established, he was transferred to another hospital for further study. Here the picture remained essentially as previously noted except that a blood culture demonstrated gram-positive cocci in short chains and many diplococci. When cultures were repeated, no cocci were found but many large gram-positive (*sic*) rods were cultured, which proved to be Friedländer's bacilli. X-ray films of the abdomen demonstrated a dense somewhat homogeneous soft-tissue mass, which filled the entire epigastrium. There was an irregular fleck of calcium to the left of the third lumbar interspace, which was thought to

have no connection with the soft-tissue shadow. The liver and spleen appeared moderately enlarged. The shadows of the kidneys and psoas muscles were distinctly seen. The gas-filled transverse colon was depressed and lay just above the pelvis. Re-examination of the abdomen with a swallow of barium outlined the stomach, which was flattened and displaced to the left and downward by the previously noted round soft-tissue mass. There was no obstruction. There was no definite evidence of intrinsic disease of the stomach, and the duodenal loop was small. The patient was started on sulfadiazine, and after eighteen hours, the blood level was 7.1 mg. per 100 cc. He had three chills during the two days' stay at the hospital, and the temperature fluctuated between 100 and 104°F. He had no specific complaints other than weakness, chills and fever. No diagnosis was established. The patient was brought to this hospital for further study and care.

The family history was not contributory. The patient lived in the country and was accustomed to drinking well water, which he obtained from his own well. This was said to be 18 feet deep, and the water was declared good. He used a privy. He stated that he had always used raw milk until three weeks prior to the present illness, when he changed to condensed milk since raw milk was difficult to obtain. He had never been immunized against typhoid fever and had been unsuccessfully vaccinated against smallpox. He smoked occasionally and did not use alcohol excessively. Ten years previously, when admitted to a government hospital for a circumcision, a scar was found on the glans penis. He denied having had a penile sore or having had gonorrhea. Serologic tests at that time were negative for syphilis.

Physical examination revealed a feverish, jaundiced young man perspiring profusely and obviously acutely ill. Examination of the lungs and heart was negative, except for a soft apical systolic murmur. The abdomen was moderately distended and tympanitic. No masses were palpable, and the liver edge could not be percussed because of abdominal tympany. The upper border of liver dullness seemed elevated, and the area of splenic dullness was increased. There was slight tenderness in the right upper and right lower quadrants. Normal peristaltic sounds were audible. The rectal examination was negative.

The blood pressure was 125 systolic, 84 diastolic. The temperature was 102.4°F., the pulse 99, and the respirations 24.

The examination of the blood revealed a red-cell count of 2,410,000 with a hemoglobin of 50 per cent and a hematocrit of 25 per cent, and a white-cell count of 17,100 with 91 per cent polymorpho-

nuclears. The urine was acid in reaction, had a specific gravity of 1.018 and showed a + test for albumin. The van den Bergh was 2.5 mg. per 100 cc., and the chloride 96.9 milliequiv. per liter. The prothrombin time was 25 seconds (normal, 20 seconds), the protein 6.1 gm., the blood sugar 94 mg. and the nonprotein nitrogen 23 mg. per 100 cc., and the bicarbonate 20.0 milliequiv. per liter. A flat plate of the abdomen demonstrated barium scattered throughout the colon, with a portion of it in the rectum. The psoas shadows were slightly indistinct. The kidneys were faintly seen. There was increased haziness throughout the upper abdomen, but no definite mass was seen. The splenic flexion of the colon was definitely lower than normal.

A course of sulfadiazine was started, and a transfusion of citrated blood was administered. The second day after admission, the patient was operated on.

DIFFERENTIAL DIAGNOSIS

DR. ALLEN G. BRAILEY: In striving to unravel this story, we might begin by asking what was the nature of the disease that made this patient ill, and it seems obvious that it was acute infection. Then we might ask in what organ or system the infection had a primary focus, and there again it seems obvious that it had to do with the biliary tree. An illness that is characterized by extreme weakness, chills, fever and the development of jaundice and anemia might well be due to pylephlebitis. The commonest source of such a pylephlebitis is the appendix. The organisms enter the portal vein and cause septic thrombi and then emboli, which lodge here and there throughout the liver and result in the production of multiple abscesses. Appendicitis may occasionally produce very few symptoms, but in this case there is no hint whatever of antecedent appendiceal infection unless one wants to attach importance to the fact that there was tenderness in the right lower quadrant. I feel hesitant about making a diagnosis of appendicitis on such slender evidence as that. Of course, pylephlebitis might rarely originate from infection elsewhere in the gastrointestinal tract. There is the note of a positive guaiac test from one hospital, so that a certain amount of occult blood had been present. I should think there were adequate reasons for that amount of blood in an inflammatory process in the biliary tree and areas surrounding the duodenum, but I suppose he might have had a small ulcer somewhere in the gut, which initiated a pylephlebitis.

Then, there is acute suppurative cholangitis, which is an interesting disease and is sometimes secondary to infection elsewhere, such as pneu-

monia, influenza or, occasionally, typhoid fever. Most commonly it follows cholecystitis. When it originates primarily in the biliary tree, it usually follows obstruction of the biliary tract, such as that from stone, tumor or echinococcal cyst or, occasionally, from intestinal worms, which may obstruct the common duct. When it is due to biliary obstruction one expects to find the biliary tree widely dilated and filled with pus. The walls are thickened, there are multiple small periportal abscesses, and the history is quite like this, with extreme weakness, a spiking septic temperature, the gradual development of jaundice and, usually, a fairly rapid fatal termination. No obstruction to the biliary tree is necessary, however; it may develop as a result of a blood-borne infection originating elsewhere or, sometimes, de novo. The organisms involved are usually streptococcus, *Staphylococcus aureus*, pneumococcus and others. I am somewhat dismayed by the bacteriologic situation. Four blood cultures were taken. Two were negative. One showed gram-positive cocci in short chains and diplococci, which I should guess were contaminants. Then one showed gram-positive bacilli that were said to be Friedländer's bacilli. This bacillus is a gram-negative, encapsulated organism, also known as *Bacillus mucosus capsulatus*, and is responsible for 5 to 7 per cent of pneumonias, which are highly fatal and characterized, among other things, by sticky tenacious sputum. It is also an interesting organism in that it is closely related to the colon group and can at times be isolated from intestinal contents. It may give rise to infection of the intestinal tract and of associated organs. I do not know that any great importance need be attached to this report of Friedländer's bacillus; but still, if it was found, it probably indicates a bacteremia. Perhaps the infectious process was due to that organism.

Now let us consider this epigastric mass of which we have this account that is so indefinite. It might, of course, have been a tumor, a lymphoma or another mass, that served as the cause of the obstruction of the biliary tract. It might also have been an extrahepatic abscess. Abscesses within the liver not infrequently, or at least occasionally, rupture through the capsule and produce such a mass. The associated infection of the common duct and gall bladder might have done likewise. Of course, if there were such an extrahepatic abscess that developed slowly enough it would have been walled off by the omentum and localized to the upper abdomen.

I do not know what this man had. On the whole, I think he had an acute suppurative cholangitis; whether this was initiated by pylephlebitis I do not know. I do not believe the surgeons knew

either. I think he was probably operated on with the idea of draining the obvious septic focus, either in the biliary tree or an extrahepatic abscess.

DR. RICHARD H. SWEET: Would it be fair to make a comment from a clinical standpoint on the description of the mass?

DR. TRACY B. MALLORY: Yes.

DR. SWEET: There was a mass. I thought that it was liver. It felt like a mass within the liver in the epigastric region and was not tender.

DR. BRAILEY: Then it might have been an intrahepatic abscess that deformed the normal liver margin. I doubt if an abscess of the liver would of itself be of sufficient size ordinarily to be palpable in the epigastrium. Do you think it might have?

DR. SWEET: Yes, it might.

DR. BRAILEY: Then perhaps the mass was all inside the liver.

DR. MALLORY: Then your preference is cholangitis with multiple abscesses in the liver?

DR. BRAILEY: I will stick to that.

DR. MALLORY: Does anyone else care to express a preference?

DR. REED HARWOOD: I think the possibility of Weil's disease should be mentioned in the list of diagnoses.

DR. MALLORY: That was thought of and serum for an agglutination test was sent to Washington; the report was negative.

DR. SWEET: If my recollection of this case is correct, the surgeon did make a diagnosis in spite of what Dr. Brailey has said. It was based largely on the history and the finding of the mass. I thought he had an abscess of the liver, and I therefore made an incision directly over the mass and found it was in the liver, chiefly in the left lobe. I aspirated it with a long needle and discovered a deep-seated abscess. It has been pointed out that liver abscesses are tender and it has been said that if one operates under local anesthesia the exact location of the abscess can be identified by palpation. We have tried that here and have found that most of the liver abscesses are not tender until they present near the surface and set up local peritonitis or pleuritis on the diaphragmatic surface. We drained the abscess, but it was obvious to me even at that time that there were many others. I could feel several suspicious spots throughout the liver.

It was my opinion that the thing started from his appendix. Whether I was influenced by the common history of appendicitis as a seat of the source, I cannot say.

DR. BRAILEY: Would not a more careful history have revealed something?

DR. SWEET: As a matter of fact, he was gone over with a great deal of care in an excellent

clinic here in Boston, where the history and examination are notoriously thorough and complete, and they did not make a diagnosis of appendicitis. He was seen by one of our surgeons at that clinic, and he did not make a diagnosis. We questioned the patient at length and thought that there was something going on in the abdomen, with the chills and fever. In a young man who subsequently had some sort of inflammatory reaction in the liver we believed that the most likely source was the appendix. By the time he was first seen, however, the process was obviously beyond the point where an operation on the appendix would have been of any use.

CLINICAL DIAGNOSIS

Liver abscess.

DR. BRAILEY'S DIAGNOSES

Acute suppurative cholangitis.

Pylephlebitis?

ANATOMICAL DIAGNOSES

Appendicitis, acute gangrenous, with rupture into root of mesentery.

Appendiceal abscess.

Pylephlebitis, suppurative: ileocolic and portal veins.

Hepatic abscesses, multiple.

Jaundice.

Splenitis, toxic.

Thrombosis of splenic vein.

Operative wound: drainage of hepatic abscess.

PATHOLOGICAL DISCUSSION

DR. MALLORY: At autopsy we found a liver filled with abscesses. On making a nick in the portal vein, pus welled from it, and then on pressing any spot in the liver more pus could be squeezed out of the portal vein, making it clear that all the multiple abscesses in the liver communicated with the portal system. Tracing down the portal radicles, we found the ileocolic vein likewise filled with pus. In the right lower quadrant was a localized peritoneal abscess, and projecting into that was the stump of an appendix from which the tip had blown off.

The liver weighed 2600 gm., and the spleen 800 gm., so that there was a lot of tissue in the upper abdomen. It is not surprising that the x-rays did not penetrate very well in that region. Our post-mortem cultures from these abscesses showed only colon bacilli and streptococci. We were unable to confirm the report of Friedländer's bacillus, which would, I think, be a very unlikely organism to find secondary to a perforated appendix.

INSTITUTE ON INDUSTRIAL MEDICINE

EVERY registered physician in Massachusetts has received a copy of the program of the postgraduate institute, "Industrial Problems in Medical Practice," to be held at the Harvard Club, 374 Commonwealth Avenue, Boston, on Saturday, November 7, under the auspices of the Committee on Postgraduate Instruction and the Committee on Industrial Health, Massachusetts Medical Society, in co-operation with the Massachusetts Department of Public Health and the Division of Occupational Hygiene, Massachusetts Department of Labor and Industries.

This attractive all-day program by authoritative speakers, which appears elsewhere in this issue of

the *Journal*, should appeal to every practicing physician, particularly in view of the fact that industrial medicine, in one or another of its many ramifications, is of paramount importance to the continuation of the war effort and a topic with which the majority of physicians are unfamiliar.

Luncheon and dinner will be served at the Harvard Club, but those who plan to attend these functions should signify their intentions in advance, since the seating and serving facilities are limited. Dr. George Leonard Schadt, president of the Society, will preside at the dinner, which will be followed by two serious but entertaining speakers. Because of the timeliness of the subject to be discussed at this meeting, all physicians are urged to attend.

NATIONAL HEARING WEEK

DEAFNESS is a national ill, and now that another war is in process, those so afflicted will increase in alarming numbers. Among the hazards to which the hearing organ may be exposed are excessive noise, gunfire, direct injury and barometric influence. Consequently, there probably has never been a time when both physicians and the laity need to be made more aware of the organized efforts that are being made for the prevention and amelioration of deafness.

The American Society for the Hard of Hearing and its one hundred and twenty-one local affiliates in the United States and Canada have done a great deal to educate and to bring about co-operation among the public, members of the medical profession and the hard of hearing. Among other things, it has accomplished a notable piece of work in fostering hearing tests and promoting lip reading in the public schools, in investigating hearing aids and advertised "cures" and in encouraging research in the medical control of deafness. The society also promotes adult lip reading, social service and vocational opportunities for the hard of hearing everywhere, thus acting as a unifying force to make life easier and better for those so afflicted.

The Boston Guild for the Hard of Hearing, the local chapter, is uniting in the nation-wide observance of National Hearing Week, October 25 to 31. This period will be devoted to the education of the public in the problems of the hard of hearing and to the demonstration of the many facilities that are provided. Because this annual event, held at the headquarters at 283 Commonwealth Avenue, is of so much value to the population as a whole, three papers in this issue of the *Journal* are devoted to the subject of hearing health. Both otologists and general practitioners should give their hearty endorsement to this constructive service for the hard of hearing.

MEDICAL EPONYM

SAHLI HEMOMETER

The hemometer was first described by Professor Herman Sahli (1856-1933), of Bern, in a paper, entitled "Über ein einfaches und exactes Verfahren der klinischen Hämometrie [A Simple and Exact Method of Clinical Hemometry]," which was read at the Twentieth Congress for Internal Medicine in April, 1902. The article appeared in *Verhandlungen des Congresses für Innere Medizin* (20:230-234, 1902). A portion of the translation follows:

After numerous attempts, I have succeeded in finding a method of converting the hemoglobin in a solution of blood into a derivative, by means of a very simple reaction, whereby stable standard solutions can be prepared and colorimetric determinations carried out. . . . The method consists simply in adding to the blood ten times the amount of one-tenth normal hydrochloric acid. After a few seconds, the solution turns deep brown and becomes a clear, brownish yellow after dilution with ordinary water. The pigment content may be colorimetrically determined by means of a similar standard solution, which can be so made as to be completely stable.

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEES ON POSTGRADUATE INSTRUCTION AND INDUSTRIAL HEALTH

The program for the postgraduate institute, "Industrial Problems in Medical Practice," to be held at the Harvard Club, 374 Commonwealth

Avenue, Boston, on Saturday, November 7, is as follows:

Morning Session

Presiding Chairmen: Dr. Dwight O'Hara
Dr. Reginald Fitz

- 8:30 *Registration.*
- 9:15 *Opening Remarks.*
- 9:30 *The Value of Pre-employment Examinations.* Dr. Daniel L. Lynch.
- 9:45 *The Personality of Industrial Applicants.* Commander A. Warren Stearns, M.C., U.S.N.R.
- 10:00 *Toxic Fumes and Gases in Industry.* Dr. Alan R. Moritz.
- 10:45 *Industrial Dermatitis.* Dr. John G. Downing.
- 11:15 *Question Period.*
- 11:30 *Round-Table Discussion on the Treatment of Burns.* Drs. Edward D. Churchill, S. Howard Armstrong, Oliver Cope and Charles C. Lund.
- 12:45 *Luncheon.*

Afternoon Session

Presiding Chairmen: Dr. Bennett F. Avery
Dr. C. Sidney Burwell

- 2:00 *Injuries to the Eyes.* Lt. Commander Edwin B. Dunphy, M.C., U.S.N.R.
- 2:30 *Examination and Diagnosis of Lane-Back Conditions.* Dr. Frank R. Ober.
- 3:15 *Recess.*
- 3:30 *Round-Table Discussion on the Modern Treatment of Wounds.* Drs. Champ Lyons, Henry C. Marble, Joseph H. Shortell and Gordon M. Morrison.

Evening Session

Presiding Chairman: Dr. George Leonard Schadt

- 6:30 *Dinner.*
- Responsibility of Physicians to Industry in Winning the War.* Lt. Colonel Anthony J. Lanza, M.C., U.S.A.
- Sterilization in Operating Rooms.* Dr. Carl W. Walter.

REGINALD FITZ, *Chairman*
Committee on Postgraduate Instruction

DWIGHT O'HARA, *Chairman*
Committee on Industrial Health

COMMITTEE ON MATERNAL WELFARE

ANALYSIS OF CAUSES OF MATERNAL DEATH
IN MASSACHUSETTS DURING 1941

SEPSIS

The tabulation printed in last week's issue of the *Journal* showed that 243 puerperal deaths occurred in Massachusetts during 1941 and that, of these, 48 patients died of sepsis. In the septic

cases, 22 were associated with abortion, of which 13 were medicolegal. It is impossible to say how many of these were criminal abortions, but there was only 1 case that might have been associated with a spontaneous abortion. There were 3 cases in which drugs were said to have been the causative factors, although there is no pharmacologic basis for the assumption that drugs play a part in abortions. Thirteen autopsies were performed, and 7 of these were in cases that followed septic abortions, 2 of which were proved to have been associated with gas-bacillus infection.

These 22 septic cases following abortion illustrate the seriousness of attempting to interfere with a normal pregnancy; and the figures, of course, do not include the far greater number of patients who, following an abortion, developed pelvic sepsis with invalidism and, oftentimes, sterility, which not infrequently demanded hysterectomy. A frank discussion of the dangers of abortion is the only way in which to bring the seriousness of this problem to the laity. Of course, all these deaths are preventable.

Of the other 26 cases allocated to sepsis, 6 were associated with normal delivery. One of these may have been caused by alveolar abscesses that were surgically drained. There was not enough evidence to comment on the value of chemotherapy in such cases.

It is gratifying to find that only 3 septic cases were associated with operative vaginal deliveries. Two patients were delivered by low forceps: in one case, sepsis developed immediately after delivery and an autopsy showed that peritonitis had been caused by a rupture of the lower uterine segment, and the other patient developed a fever on the third day after delivery and in spite of apparently intelligent chemotherapy succumbed nineteen days later. The third case in this group was a patient, six and a half months pregnant, in whom a cicatricial cervix made normal dilatation impossible; insertion of a Voorhees bag was attempted unsuccessfully, and sepsis developed intra partum; delivery was consummated by a vaginal cesarean section, and the patient died a few hours later.

Fifteen septic cases were delivered by cesarean section. Of these, 3 had the benefit of autopsy: in two, the diagnosis of peritonitis was confirmed, and in the third, adynamic ileus was apparently the cause of death, without sepsis being the underlying factor. One section was done because of a placenta previa. There were 3 cases in which cesarean sections had been previously performed. The first patient, who had had acute heart failure and chronic bronchitis associated with myocarditis in 1931, was given spinal anesthesia to prevent

inhalation irritation; however, sepsis developed. Another patient had no apparent ante-partum infection but developed sepsis immediately following a planned cesarean section. There is nothing of particular interest about the third case.

Of the 2 remaining septic cases, one was proved at autopsy to have had a double uterus and was associated with toxemia, and the other was complicated by a placenta accreta. The latter patient delivered herself of a macerated fetus, but the placenta did not come away. There was no bleeding, the placenta remaining in situ until the day following delivery, when the patient's temperature rose to 103°F. An accreta was diagnosed after an unsuccessful attempt to remove the placenta; hysterectomy was performed, and general peritonitis developed.

It is gratifying that bungling operations played no part in these septic deaths. The handling of the case in which the Voorhees bag was employed unsuccessfully in a patient, six and a half months pregnant, who was finally delivered by vaginal cesarean section after sepsis had developed, is, of course, open to criticism. The case of ruptured uterus associated with sepsis was not appreciated until the autopsy was performed. There were no versions in the entire series.

Three points of particular interest evolve from this study: the small number of cases associated with injudicious operating; the increased number of autopsies over any previous year; and the disturbing fact that fatal sepsis occurred in 3 cases of planned repeat cesarean section, explainable only by inadequate aseptic technic—such deaths are regrettable and should never occur.

DEATHS

BLAKELY—DAVID N. BLAKELY, M.D., of Brookline, died October 15. He was in his seventy-sixth year.

Born in Campton, New Hampshire, Dr. Blakely attended Dartmouth College. After four years in Aintab, Turkey, he returned to this country and entered Dartmouth Medical School, receiving his degree in 1896. He spent four years at the Boston City Hospital and then practiced in Boston for several years. Dr. Blakely was assistant medical director of the New England Mutual Life Insurance Company at the time of his death. He was a fellow of the Massachusetts Medical Society and the American Medical Association. Dr. Blakely was active in the affairs of the Society for many years, having served as a member of the Council from 1918 to 1940 and as chairman of the Committee on Membership and Finance from 1922 to 1938.

His widow, a daughter, a son, a sister and a brother survive him.

GORMAN—JOHN W. GORMAN, M.D., of Brockton, died July 28. He was in his sixty-fifth year.

Dr. Gorman received his degree from the College of Physicians and Surgeons, Boston, in 1900. He was a former member of the Massachusetts Medical Society.

CORRESPONDENCE

THE APPROACHING REFERENDUM

To the Editor: On November 3 the voters of Massachusetts will have an opportunity of deciding at the polls whether physicians are to be allowed to practice their profession in accordance with the best medical standards or whether an old blue law on the statute books of the Commonwealth will continue to stand in the way of their saving the health and even the lives of some of their patients. The referendum to be voted on means just this: duly registered physicians shall be permitted to give contraceptive advice to *married* women whose *health or lives* will be jeopardized by pregnancy.

It is an established medical fact that pregnancy imposes a strain on a woman and that in the presence of many diseases (for example, heart disease, nephritis, tuberculosis, certain psychiatric conditions and so forth) continuation of pregnancy or repeated pregnancies may seriously damage the health or even kill some of these women.

It would seem superfluous, therefore, to argue the obvious desirability of this measure, especially before a medical audience, were it not for the devious, obscurantist and fallacious arguments that have been spread as a veritable school of red herrings across the path of truth and that may unfortunately confuse many people; these should be briefly answered.

It is believed by the Catholic Church that such contraceptive methods violate God's will and hence must not be used under any circumstances. This law will in no way interfere with those holding these beliefs; as the state Supreme Court itself has stated, the law is purely permissive, no Catholic physician or patient need use it. It merely extends to those not holding this religious belief a vital medical right, which a minority religious group would withhold from them.

It has been charged that the referendum promotes disunity and thus impairs the war effort. Actually the opposite is the case: true unity and true democracy only exist when the civil and religious liberties of all are protected and mutually respected. It is the opponents of this measure who are sowing disunity by perpetuating intolerance, and they are trying to maintain an economically undemocratic situation whereby the poor people of the State, who can only be adequately cared for in clinics, are deprived of medical help, which many of the well-to-do are now obtaining in one way or another.

The charge that this law will increase license and promiscuity is equally absurd, and is by implication a slur on the honor of the medical profession. Since it will apply only to married women for health reasons, any advice given to any other women will have no more legal sanction than exists at present. The hypocrisy of those making this charge is evident from the fact that they have never in concerted fashion publicly opposed the sale of condoms and similar articles which, it is well known, are the contraceptives chiefly used in sexual promiscuity; their sale has been declared legal because they can be sold ostensibly "for the prevention of disease." This measure will improve moral standards because it will give married women who need it the right to obtain, and physicians the right to prescribe, this advice *legally*.

Another accusation is that this law will lead to race suicide. It is patent that the number of healthy children that the women who will come under this law will fail

to produce is extremely small, and will be more than overbalanced by the increased number of viable children who will be born when sick mothers can properly space their children and limit the size of their families. Statistics prove our point: for example, in Ireland, where birth control has long been outlawed by church and state, the population has been cut in half during the last one hundred years, the most catastrophic birth decline of any nation in the world; on the other hand, in Holland, which pioneered in public birth-control clinics in 1880, the population has doubled in 60 years, owing to a much higher marriage rate and very low infant and maternal mortality rates. Other factors than the legality of contraceptive advice determine birth rates.

We often think with pride that Massachusetts ranks high in the medical world. But in this case all states in the Union except Massachusetts and Connecticut accord doctors the right to give needed advice. The challenge has been thrown down to the people of Massachusetts, and especially to physicians. It is an issue that far transcends the particular point with which this referendum deals. The issue is, Shall doctors be denied the right to practice their profession according to the highest medical standards and in accordance with the dictates of their own consciences?

NOTICES

ANNOUNCEMENTS

DR. HENRY R. VIETS announces the removal of his office to 262 Beacon Street, Boston, on November 1.

The Bacteriological Laboratory of the Health Department of the City of Boston has been transferred from Room 1101, City Hall Annex, to new quarters in the Haymarket Square Relief Building, where the entire personnel of the Health Department will shortly be located. The Bacteriological Laboratory can be reached by the same telephone numbers, and maintains the same bacteriologic and serologic services, with the advantage of modern facilities and equipment.

MASSACHUSETTS GENERAL HOSPITAL

A meeting of the Hospital Research Council will be held in the Bigelow Amphitheater of the White Building on Tuesday, October 27, at 5 p.m.

PROGRAM

Some New Data on Oxygen Poisoning. Drs. C. M. Williams and H. K. Beecher.

Notes on the Action of Colchicine. Dr. Austin M. Brues.

The Relation of Vascular Disease to the Hypertensive State based on a Study of Renal Biopsies from 100 Hypertensive Patients. Drs. Benjamin Castleman and R. H. Smithwick.

17-Ketosteroids Excretion in Normal and Abnormal Children. Drs. N. B. Talbot and A. M. Butler.

NUMBER 18

ECZEMA AND PRURITUS IN THE AGED*

LEONARD E. ANDERSON, M.D.†

SPRINGFIELD, MASSACHUSETTS

SINCE the average span of life has increased steadily and the population has come to be made up of a larger proportion of older people, medicine in general has paid more attention in the past decade or so to the problems presented by this group, and the term "geriatrics" has become commonplace in medical literature. Numerous problems peculiar to old age have been subjected to special study, and articles on a wide range of these have been published. Eczema and pruritus in the aged have not received a great deal of special attention in the literature largely because they present essentially the same problem in old people as in other age groups except for the clinical picture produced by senescent skin changes themselves.

The words, "eczema and pruritus," embrace a very wide field and in their discussion a whole treatise on general dermatology could properly be included, since a majority of dermatoses are eczematous or dermatitic and most are pruritic. This paper, however, is limited to the chief conditions producing a more or less generalized pruritus.

It might be well to make a few prefatory remarks about the mechanism of "itch." Itching is a distinctive cutaneous sensory disturbance peculiar to the integument and does not depend on the presence of cutaneous eruption for its existence. It is a complex sensation composed of a blending of touch and pain, and can be perceived only when both the touch and pain transmission tracts are functioning. It is apparently largely a thalamic rather than cortical sensory sensation and can occur in sleep and semiconscious states. Scratching during sleep in many of the pruritic dermatoses is, of course, a common observation. Perception of itch depends on an attention factor and a threshold susceptibility factor, the former con-

trols the slight sensations present in even normal skins, and these are therefore not perceived as itch. In long-standing pruritus, the threshold is lowered, and fatigue states affect the attention factor, so that the treatment problem is not an easy one.

It should first be said that a diagnosis of senile eczema or pruritus is too often made just because the patient is aged. Instead, as in younger patients, one should attempt to differentiate and classify the aged patient's condition. Even when one is presented with the picture of pruritus without gross cutaneous change in a thin, dry, aged and atrophic skin, the diagnosis of senile pruritus should not be made too readily without a consideration and elimination of other possible explanations; the patient may have subthreshold jaundice, for example, from early obstruction by a cancer.

TYPES OF PRURITUS

Senile pruritus occurs in both men and women, usually over sixty years of age. This age is an arbitrary one, since, obviously, some patients have senescent cutaneous changes beginning at an earlier age and others have little discernible atrophy even in the sixties. The exciting cause of senile pruritus is atrophy of the entire thickness of the skin, including its appendages, which results in a thin, dry, irritable skin and leads to generalized itching.

Psychoses and psychoneuroses are primarily psychiatric rather than dermatologic problems, but the average practitioner can certainly do more even in an anxiety neurosis than dismiss the patient with the statement, "It's all in your imagination." Acarophobia (fear of scabies or imaginary infestation with mites or scabies) should be recognized because much can be accomplished by authoritative and convincing reassurance. A patient with acarophobia almost invariably picks

*Presented at a meeting of the Section of Dermatology and Syphilology of the Massachusetts Medical Society, Boston, May 17, 1942.
†Assistant dermatologist, Springfield Hospital; dermatologist, Western Memorial Hospital.

from the skin pieces of lint, crusts and so forth, and is convinced that these are mites; he usually brings to the physician some of these specimens in a pillbox or carefully wrapped in paper. Even if the nature of the specimen is grossly obvious, it should be studiously examined with a lens or microscope, preferably in the presence of the patient. If the true situation is then explained and the patient reassured, this in itself effects a cure in most cases unless there is a deeper underlying "sense of guilt" or other psychiatric problem.

Diabetes can be diagnosed or ruled out by urinalysis and blood-sugar determination, and the glucose-tolerance test, if indicated. Diabetes does not produce a distinctive eruption in patients who have pruritus because of it. Carbuncles, furuncles and other pyogenic infections are likely to occur, but may be entirely absent in the patient presenting himself because of pruritus. Necrobiosis lipoidica diabetorum is a rare dermatosis observed in diabetic or prediabetic patients, but its appearance is so distinctive that it could hardly be mistaken for eczema and need not be discussed here.

Jaundice is a well-known cause of generalized itching, and no one would fail to recognize this relation in a fully developed icterus. However, it must be remembered that pruritus can be present and troublesome when the skin has no observable yellowish tint and the scleras appear normal. An icteric index determination is helpful, and a full medical workup from the standpoint of the biliary system should be done if indicated.

The *lymphoblastoma group* includes Hodgkin's disease, lymphatic and myelogenous leukemia, lymphosarcoma and mycosis fungoides. These are fortunately rare, but those who practice dermatology have at some time seen one or another of these in a patient who was considered to have "eczema." The clinical pictures are not distinctive enough to warrant taking time to attempt to describe or differentiate them, except in the tumor stage of mycosis fungoides. But even in the early stages of mycosis fungoides, which may last for years, a definite diagnosis cannot be made on clinical appearance alone. The type of patient who comes under the scope of this discussion usually presents a fairly extensive erythrodermia or exfoliative dermatitis. The skin may show definite infiltration, or this may not be evident; there may be an accompanying lymphadenopathy, and the pruritus may be intractable. Diagnosis depends on the study of the cellular constituents of the blood and on biopsy of the skin and lymph nodes. It must be borne in mind, of course, that the skin can show typical and pathognomonic leukemic infiltration in the presence of a normal picture in the circulating blood.

Dermatitis hiemalis (winter itch) and *bath dermatitis* can, for convenience, be considered together. They occur at any age, but the senescent dry atrophic skin is especially vulnerable. Although some persons apparently react with pruritus to cold itself, most patients have their dermatitis or pruritus because of excessive defatting and drying of their skins by means of soap and water and the dry overheated air of dwellings. The trunk and the extensor surface of the extremities are especially involved. Only the evidence of scratching and a mild ichthyotic change may be present, or a patchy dry superficial erythematous-squamous dermatitis, at times even eczematized. In warm weather, the condition is ameliorated or disappears because the overdried air factor is no longer operative, and perspiration partly assumes the role of lubrication carried on by sebaceous activity in younger skins.

Urticaria is distinguished by the presence of wheals, with which everyone is so familiar that the eruption cannot be confused with eczema. However, the persistence of urticaria is due to recurring crops of lesions, and the individual lesion may reach full development and undergo involution in a few hours, so that no trace of wheals may be present at the time of examination. A careful history, however, and subsequent observation establish the diagnosis and rule out senile pruritus. Giant hives or angioneurotic edema is a not infrequent accompaniment of chronic urticaria.

Drugs, such as morphine and cocaine, taken by addicts can produce generalized pruritus. History and concomitant findings point the way to the diagnosis. The various drugs used therapeutically that can produce a dermatitis medicamentosa or pruritus are too numerous to list in a paper of this scope.

Parasites that are most commonly encountered in this vicinity include scabies and pediculi. Scabies is produced by a macroscopically visible mite that burrows into the skin to deposit its ova. When a classic burrow is found, diagnosis is easy. Usually, however, scratching destroys these, and one must depend on the history and the distribution of the eruption. Itching is most intense after the patient is in bed, when the warmth of the bedclothes stimulates the mites to activity. The thin-skinned regions are characteristically involved, and the sites of predilection are as follows: finger webs, flexor surfaces of the wrists, axillary folds, waistline, buttocks, nipples (in women) and penis (in men). The face and neck are spared except in infants. The mite can be recovered from a burrow, but this is by no means as easy as most writers lead one to believe. There

are three common kinds of pediculi: *Pediculus capitis*, *P. corporis* and *P. pubis*. The first attacks only the scalp, and the diagnosis is made by the finding of the adult louse or "nits," which are sacs containing the ova and are attached to hair shafts. *P. pubis* attacks pubic hairs primarily, but is often found in the axillas, occasionally on the hairs of the chest and abdomen, and rarely in the eyebrows and lashes. The adult louse is easily seen with a lens at the base of a hair, with its head buried in the follicle. The nits are attached to hairs but are smaller than those of head lice. *P. corporis* does not live on the skin but in the patient's clothing, especially about the seams. It produces a nondescript scratch dermatitis especially about the shoulders, interscapular region, waistline and upper portions of the buttocks; diagnosis is confirmed by examination of the underclothes for the parasite. Chiggers, straw itch, tick bites and so forth are not prevalent in Massachusetts.

Psoriasis can be very pruritic when it is acutely generalizing. If small discrete lesions are present, the characteristic micaceous scale and capillary bleeding points can usually be found in well-developed lesions. When the process has turned into a universal exfoliative dermatitis, as it does only rarely, diagnosis cannot be made without the help of biopsy or previous knowledge of the pre-existing psoriatic eruption.

Lichen planus is characterized by pruritus, but diagnosis is easy even in extensive eruptions because of the presence of violaceous polygonal flat lichenoid papules with a characteristic sheen and almost no scale. When the papules are large or confluent, fine grayish lacelike streaks (known as Wickham's striae) are usually easily seen and are practically pathognomonic. In the extremely rare case in which lichen planus evolves into a universal exfoliative dermatitis, the diagnostic problem is the same as in psoriasis.

Dermatitis herpetiformis is a rare dermatosis of multifactorial character but showing almost always some herpetiform, grouped vesicles. It runs a chronic course, and the skin tends to become pigmented at the sites of involvement. It is often extensive but not universal, and sites of predilection are the extensor surfaces of the extremities, the midline of the back, the shoulders, and the back and sides of the neck. Diagnosis is suggested by chronicity, pigmentation and herpes-like grouped vesicles or blebs.

Contact sensitivity to wool or other articles of clothing can produce pruritus or eczematous eruptions. Careful history taking and indicated patch-test studies are essential for a positive diagnosis.

TREATMENT

In general, treatment should be aimed at the causative and contributing constitutional and psychoneurogenous factors in generalized itching, and antipruritics used as adjuncts.

Of the antipruritics, phenol, menthol, camphor and liquor carbonis detergens are in widest use and least likely to do harm. The cocaine derivatives include benzocaine, nupercaine, butyn, diathane hydrochloride and holocaine, all of which not uncommonly produce contact dermatitis after the patient's skin has developed a sensitivity to them, and should be avoided if possible. Witch-hazel water and alcohol have antipruritic value, and plain hot or ice water often controls a localized itching bout. The cornstarch or oatmeal bath is useful in generalized itching and should usually be followed by the application of an oily lotion.

In senile pruritus and other pruritus without dermatitis, local medication in the form of a lotion may be employed. Although many more elegant formulas can be made up, the unavailability of their newer ingredients in neighborhood pharmacies is a distinct disadvantage so that the time-honored Pusey's calamine liniment is still a useful preparation:

R	Liquid phenol	1.0 cc.
	Oil of bergamot	1.3
	Powdered tragacanth	5.3 gm.
	Zinc oxide	
	Calamine	aa 30.0
	Olive oil, 150.0 cc., or	
	liquid petrolatum	90.0 cc.
	Water	q. s. ad 480.0

Make an emulsion of the oil with tragacanth. Add gradually, with constant shaking, the other ingredients already mixed.

For patients with winter or bath itch, the cornstarch bath is substituted for soap bathing, and the following lotion is prescribed:

R	Starch	8.0 gm.
	Glycerin	4.0
	Witch-hazel water	16.0 cc.
	Oil of sweet almond	60.0
	Olive oil	
	Lime water	aa q. s. ad 240.0

If the antipruritic effect needs to be enhanced, 1 to 2 per cent phenol and 0.5 or 0.25 per cent menthol or camphor may be added; or the following lotion, which contains tar, may be substituted:

R	Phenol	2.4 cc.
	Camphor	1.2 gm.
	Glycerin	2.4 cc.
	Liquor carbonis detergens	7.2
	Starch	12.0 gm.
	Olive oil	
	Lime water	aa q. s. ad 240.0 cc.

For the dry erythematousquamous dermatitic patches in these patients, the following ointment may be prescribed:

℞ Salicylic acid	0.3 gm.
Liquor carbonis detergens	3.0 cc.
Aquaphor	
Rose water ointment āā q. s. ad	30.0 gm.

If lichenification is present in chronically scratched areas, 5 to 10 per cent oil of cade or pine tar may be used in the above formula; or crude coal tar ointment may be prescribed as follows:

℞ Crude coal tar	2.0 cc.
Zinc oxide	2.0 gm.
Mix and let stand 24 hours	
Starch	8.0
Yellow petrolatum q. s. ad	30.0
Make an ointment	

If the patches are frankly eczematized, the following formula is useful:

℞ Ichthyol	0.9 gm.
Zinc oxide ointment	30.0

For scabies, an ointment containing sulfur and balsam of Peru is efficacious:

℞ Precipitated sulfur	12.0 gm.
Balsam of Peru	12.0 cc.
Lanolin	30.0 gm.
Benzoinated lard q. s. ad	120.0

For children, betanaphthol may be substituted for the sulfur in a strength of 3 to 5 per cent, an equal concentration of Peru balsam being employed. Successful cure depends on careful instruction of the patient. A hot soap bath should be taken the first night, and all crusts and vesicle tops scrubbed off; the ointment should then be rubbed into the entire skin surface from the neck down. On the next morning and night, the ointment is reapplied, and on the following morning, a hot soap bath is taken and all underclothing and bed linens cared for by boiling or dry cleaning. One of the above oily lotions may be used if there is irritation from the treatment course. One course rarely fails to cure and, in any event, should not be repeated in less than ten days.

P. capitis is best treated by the time-honored turbaning of the scalp with equal parts of olive oil and kerosene overnight, followed by shampoo and removal of the nits by soaking with vinegar and the use of a fine-tooth comb. *P. corporis* requires attention to the clothing and one of the above lotions for the scratch dermatitis. *P. pubis* should not be treated with blue ointment because of the intense irritation provoked, but mercury may be used as a 1:500 solution of the bichloride and the nits soaked off with vinegar.

Generalizing psoriasis must be treated with caution, and no vigorous antipsoriatic medications should be employed. Autohemotherapy is useful at intervals of three to seven days; the starch bath may be used and followed in the guttate variety by an ointment containing 2 per cent each of salicylic acid and ammoniated mercury in a cold cream or Aquaphor base.

In lichen planus, irradiation is of distinct help but should be employed by an expert only. Mercury or arsenic by mouth or injection is indicated. A combination of the two metals in the form of mercury salicylarsenate (Enesol) is widely used intramuscularly, but occasional reactions occur. Local applications are of little avail and are indicated only to control pruritus.

Dermatitis herpetiformis is notoriously resistant to treatment, although some promising results have been obtained with the sulfonamides. Sulfur baths (a 2.5-cm. cube of commercial sulfurated potash being added to the tub), antipruritic lotions and arsenious acid by mouth in the form of Asiatic pills often produce a remission.

SUMMARY

Eczema and pruritus in the aged present the same problems as in other age groups, in addition to the factor of dry atrophic skin with increased vulnerability.

Generalized pruritus is produced by numerous conditions, and the diagnosis of "senile pruritus" should be made only after other causes have been searched for and excluded.

Therapy should not only consist of local applications but also aim at the underlying factors.

20 Maple Street

INTRACRANIAL ANEURYSM OF THE INTERNAL CAROTID ARTERY*

T W BOTSFORD, MD†

BOSTON

RECENTLY, a patient suffering from an intracranial aneurysm of the internal carotid artery entered the Peter Bent Brigham Hospital. So much interest was aroused from the study of this patient that I was stimulated to search out and review all similar cases admitted to the hospital, as well as those reported by others, in an effort to arrive at the proper management of this unusual condition. This paper is presented to summarize the findings and to report in detail on the most recent case.

CASE REPORT

A 51-year-old married woman entered the Surgical Service on June 9, 1941, complaining of a buzzing noise over the left side of her head of 4 months' duration. The past history was essentially irrelevant. The patient had always enjoyed good health. There was no history of syphilis.

Four months before entry, the patient awoke in the morning with a severe headache. She had had numerous headaches for many years and did not consider it unusual. That night, when she bent over to untie her shoelaces she suddenly had the sensation of a light bulb bursting in her head. This sensation lasted only a few seconds, but immediately afterward, for the first time she was conscious of a rhythmic buzzing noise over the entire left side of her head. This noise was present constantly thereafter and often kept her awake at night. Four weeks before admission, she noticed that she had double vision, and 3 weeks later, she had a single momentary sensation like an electric shock, in her right arm. There were no convulsions, hemiparesis or bouts of unconsciousness at any time.

Physical examination on admission showed an intelligent, well-developed and well-nourished woman in no distress. There was a loud bruit, systolic in time over the left side of the head anteriorly and over the left common carotid artery. A systolic thrill was palpable over the left common carotid artery. The lateral rectus muscle of the left eye was paralyzed, but the other extraocular muscles were normal. The pupils were equal and reacted normally to light and accommodation. Ophthalmoscopic examination showed normal eye grounds, and the visual fields were normal. The blood pressure was 130/90. Abdominal and pelvic examinations were negative. Complete neurologic examination was negative except for paralysis of the 6th cranial nerve on the left.

Examination of the blood showed a red cell count of 4,800,000 with a hemoglobin of 80 per cent (Sahli), and a white cell count of 6700. The blood volume was normal. Lumbar puncture showed normal pressure and normal dynamics. The cerebrospinal fluid was water clear and showed no increase in white cells and no red blood cells. The spinal fluid protein was 35 mg per 100 cc. Wassermann and Hinton tests on the blood and spinal fluid were

negative. X-ray films of the skull, chest and heart showed no abnormalities.

The impression on admission was that the patient had an intracranial aneurysm of the left internal carotid artery.

While the patient was in the hospital, the left common carotid artery was compressed for 20-minute periods on two occasions, without noticeable mental or physical changes. It was then believed that she could stand ligation of the left internal carotid artery.

Under local anesthesia, the left internal carotid artery was exposed. Diodrast was injected, and films of the skull were then made. Following this, the artery was divided, and the ends were ligated with silk. The murmur and thrill immediately disappeared, both subjectively and objectively. The report of the x-ray films of the skull was as follows:

Films of the skull in the operating room after injection of 70 per cent Diodrast show the left internal carotid artery well outlined, appearing normal up to the area beside the sella, where there appears to be vascular dilatation 1.5 cm in diameter. The upper edge of this, however, is not raised above the sella as is usual in aneurysms. The internal carotid artery beyond this point is not visualized.

After operation, the patient made an uneventful recovery. A minimum diplopia continued, as did the left 6th nerve palsy, but the bruit remained absent. At follow-up 7 months later, the bruit was still absent, and there had been a constant decrease in the patient's diplopia until it occurred only when she turned sharply to the left. The patient had learned to avoid this maneuver and therefore was not troubled by diplopia. The vision in the left eye was equal to that of the right, but there still remained weakness in the external rectus muscle on that side, presumably evidence of continued slight impairment of the 6th nerve function.

PREVIOUS CASES

This review of cases includes only the aneurysms located at the junction of the internal carotid artery, either at the circle of Willis or in close proximity to that region. Forty such patients, including the one reported above, have entered this hospital in the last twenty-eight years. Twenty-one cases were verified at operation or autopsy, and 19 were diagnosed clinically. One case, in addition, was verified by Diodrast injection of the internal carotid artery. Over three fourths of the cases occurred in females; there were 31 females and 9 males in the group. The cases showed a marked peak in the sixth decade of life (Fig. 1). There were twenty-seven aneurysms on the right side and thirteen on the left.

The symptoms of 36 patients, exclusive of the 4 whose aneurysms were found incidentally at autopsy, were abrupt in onset in 19 cases and in-

*From the Surgical Clinic, Peter Bent Brigham Hospital.

†Instructor in surgery, Harvard Medical School; fellow in otology, Peter Bent Brigham Hospital.

sidious in 17. Headache and eye complaints were always the leading symptoms.

The third cranial nerve was involved in 23 cases (64 per cent): alone in 5 cases; with the fourth and sixth nerves in 9 cases; with the fifth nerve in 4 cases; with the fourth nerve in 2 cases; with the sixth nerve in 1 case; and with the fourth, fifth

this patient died six months later, and autopsy showed thrombosis of the aneurysm. Of the other 2, one patient was alive and asymptomatic at the end of five years, but has not been traceable since; the other is alive seven months after operation and free of the bruit, although she still has a residual sixth-nerve palsy.

In the untreated group, 9 patients (23 per cent) died of rupture of the aneurysm, 14 died without the exact cause being known, and 14 are unaccounted for, since they did not respond to follow-up inquiries.

DISCUSSION

Intracranial aneurysms have been the subject of considerable interest in the literature of the past few years. Some of the cases in this series have been reported by Symonds,⁴ Doubler and Marlow,⁵ Viets⁶ and Sosman and Vogt,⁷ because of interest in clinical manifestations and x-ray findings. Not until recently has an accurate clinical diagnosis of intracranial aneurysm been made. The gradual accumulation of knowledge concerning the disease and roentgenologic studies^{7, 8} of the appearance of intracranial aneurysms, including cerebral arteriography introduced by Moniz,⁹ have made this possible.

The syndrome of headache, either acute or recurrent, associated with paralysis of the third, fourth, fifth and sixth nerves, either individually or in combination, is strongly presumptive evidence of intracranial aneurysm of the internal carotid artery. The bruit must be searched for and, if present, is pathognomonic of the condition. Plain x-ray films of the skull may show calcification in the wall of the aneurysm. These areas of calcification are usually fine curvilinear shadows. In addition, there may be erosion of the bone adjacent to the aneurysmal sac.⁷ So far as I know, there is no danger in injecting Diodrast into the internal carotid artery to visualize the aneurysm, and the vessel can be ligated at the same time.

Rupture of the aneurysm, in some cases, may be the first manifestation of the difficulty: there is sudden, severe pain along the distribution of the trigeminal nerve as the blood is spilled over the gasserian ganglion, and coma usually follows. On examination, the neck is stiff, and Kernig's sign is positive. If lumbar puncture is done, the spinal fluid is found to contain fresh red blood cells. Death usually follows rupture, although Fearnside¹ reported that 41 per cent of his patients had one or more bouts of leakage from the aneurysm, without death.

The treatment of intracranial aneurysms has been directed toward the induction of thrombosis of the aneurysm. This has been attempted by

FIGURE 1. Incidence of Aneurysms at the Junction of the Internal Carotid Artery, according to Age Groups.

and sixth nerves in 2 cases. The sixth nerve only was paralyzed in 2 cases, the fourth and fifth in 1, and the fourth, fifth and sixth in 1.

Although these 27 patients presented ophthalmoplegia of varying degrees, of the 9 cases remaining, 3 were totally blind, 3 had homonymous hemianopsia, and 3 entered in coma. Nineteen patients had hypertension, and 17 had normal blood pressure. The blood Wassermann reaction was negative in all. The absence of syphilis in patients with intracranial aneurysm, in contrast to patients with aneurysms elsewhere, has been pointed out by others.¹⁻³

The presence of a bruit in the head was carefully searched for, both subjectively and objectively. Only 3 patients noticed a "buzzing noise" in the head, and in only 1 was it the chief complaint. In addition to these, a bruit over the skull was discovered by auscultation in 3 cases, so that in 6 (15 per cent) of the cases this sign was present.

The diagnosis on admission in 28 cases was intracranial aneurysm; in 5 cases, pituitary adenoma; and in 3 cases, meningioma. The neighboring symptoms, sometimes caused by a large intracranial aneurysm, may easily simulate a brain tumor, as pointed out by Symonds.⁴ In 1 case, not included in this series, a diagnosis of intracranial aneurysm was made, but at operation elsewhere the source of the trouble was found to be a chromophobic adenoma of the pituitary gland.

Only 3 patients were subjected to surgical therapy. In each case, the internal carotid artery was ligated in the neck. In 1 case, the aneurysm was also opened, and muscle was packed into the sac;

direct attack on the aneurysm, by ligation of the cervical portion of the internal carotid artery and by ligation by clip of the vessel distal to the aneurysm intracranially, in addition to ligation of the internal carotid artery in the neck. The direct attack on the aneurysm is usually impossible and is most dangerous.

Ligation of the cervical portion of the internal carotid artery for aneurysm was first practiced by Sir Astley Cooper in 1805. It is not a hazardous procedure in selected cases, and following it, a number of patients with intracranial aneurysm have had symptomatic relief. Schorstein,¹⁰ who collected 60 cases of intracranial aneurysms for which the internal carotid artery had been ligated, found that in infrachnoid aneurysms ligation was a benign procedure unattended by neurologic complications or death. However, in supraclinoid aneurysms, there was a 13 per cent mortality. This mortality he ascribed to the fact that there had been recent leakage from the aneurysm or compression of the basal arteries.

Before the internal carotid artery is ligated, it should be totally occluded by pressure for ten minutes, as recommended by Matas¹¹ and by Dandy,¹² to determine whether or not there is any untoward effect on the cerebral circulation. Occasionally, even after the occlusion test, a late effect may follow ligation of the artery. The preoperative condition of the cerebral circulation is all important in the decision of whether the patient will tolerate ligation of one internal carotid artery.

Dandy, in 1937, first trapped an intracranial aneurysm between a silver clip distal to it and a ligature around the cervical portion of the internal carotid artery. Since then, a few similar successful cases have been reported.¹²⁻¹⁴ It is a difficult procedure at best and not always possible; nevertheless, it is the rational method of approaching the disease.

SUMMARY AND CONCLUSIONS

A case of intracranial aneurysm of the internal carotid artery, associated with a bruit over the

head and a sixth-nerve palsy, is reported. Treatment consisted in ligation of the cervical portion of the internal carotid artery.

The cases of 40 patients with aneurysm of the intracranial portion of the internal carotid artery who entered the Peter Bent Brigham Hospital in the last twenty-eight years were reviewed.

Headache and palsy of the third, fourth, fifth and sixth nerves were the leading clinical signs and symptoms. A bruit over the head was present in 15 per cent of the cases.

Ligation of the cervical portion of the internal carotid artery is advocated, provided that the cerebral circulation is sufficient after occlusion of the artery for ten minutes.

Trapping the aneurysm between an intracranial clip and a ligature around the cervical portion of the intracranial aneurysm may be attempted, but is not always possible to carry out.

Cerebral arteriography is a safe and reliable procedure to verify the presence of the aneurysm.

GASTROINTESTINAL SYMPTOMS AND INGUINAL HERNIA*

ROBERT S. MYERS, M.D.,† AND ROBERT ZOLLINGER, M.D.‡

BOSTON

BEFORE operation is advised for an inguinal hernia, it is an established practice to make certain that the patient does not also present evidence of chronic pulmonary disease or partial urinary obstruction. Little significance, however, has been attached to gastrointestinal symptoms. Such symptoms occurring in patients with inguinal hernia should receive careful study. There is a tendency to attribute these complaints to the presence of the hernia and to advise repair without further investigation. This, we believe, is a dangerous policy, for not infrequently some other process, such as ulcer or cancer of the gastrointestinal tract or gall-bladder disease, is masked by the more obvious complaint of hernia.

Much of the literature suggests that gastrointestinal symptoms, such as epigastric distress, abdominal cramps, flatulence, nausea and vomiting, may be the result of an inguinal hernia that has never been incarcerated or strangulated. An uncomplicated inguinal hernia is said to produce distress varying from uneasiness in the epigastrium to actual abdominal pain in the region of the umbilicus. Nausea has been alleged to result from traction on the mesentery, and reflex disturbances of digestion—cramps, intestinal pain and gas—are described.¹⁻⁴

On the other hand, there are those, like Behan,⁵ who believe that pain, usually of a dragging nature, is of minor importance as a symptom of uncomplicated inguinal hernia. Andrews and Bissell⁶ state that in at least 90 per cent of all cases of hernia pain is totally absent. In their opinion, the relief of chronic indigestion supposed to be caused by hernia has proved to be very disappointing, for it generally persists after the hernia has been surgically cured.

There are thus two opposing schools of thought: one believing that gastrointestinal symptoms can be the result of simple uncomplicated inguinal hernia; and the other that gastrointestinal symptoms are not to be explained by such an obvious reason.

Within recent months, our attention has been arrested by 2 cases of gastrointestinal cancer, overlooked at the time of herniorrhaphy. This led us to review 200 consecutive cases of uncomplicated

inguinal hernia coming to operation. In studying these cases, we found that in 81, or 40 per cent, there were no complaints other than the presence of a hernia; 82 patients, or 41 per cent, had groin pain, and 37, or 18 per cent, had definite gastrointestinal symptoms that required investigation (Table 1). Thus, approximately one fifth of the

TABLE 1. *Gastrointestinal Symptoms in Cases of Operable Inguinal Hernia.*

Total	200	

patients had symptoms referable to the gastrointestinal tract, and it is with this group that we are primarily concerned.

Table 1 shows that 22, or 59 per cent, of the 37 patients with gastrointestinal symptoms had a plausible explanation for their complaints of abdominal pain, gas, nausea or vomiting. These were the following: momentary attacks of recognized incarceration, whose reduction relieved all symptoms; epigastric distress treated successfully by diet and alkalies that were prescribed by the family physician; and gall-bladder disease and peptic ulcer, proved by x-ray examination.

Fifteen, or 41 per cent, of these patients presented vague but persistent gastrointestinal symptoms for which no cause was found prior to operation. There was no history of incarceration; diet and medical treatment brought no relief; and x-ray examination was negative in the few cases in which it was employed. Although it is true that 11 patients in this group were relieved of symptoms following herniorrhaphy, 2 of the 15 demonstrated gastrointestinal cancer as the true basis for their complaints. If the error of first performing herniorrhaphy on a patient who also suffers from carcinoma is to be avoided, all unexplained gastrointestinal symptoms must have a thorough appraisal before operation. A review of the following cases clearly shows the need for intensive investigation of gastrointestinal symptoms in the presence of inguinal hernia.

*From the Surgical Clinic, Peter Bent Brigham Hospital.

†Instructor in surgery, Harvard Medical School; associate junior surgeon, Peter Bent Brigham Hospital.

‡Major, M.C., A.U.S.; formerly, surgeon, Peter Bent Brigham Hospital.

CASE 1 A 48 year-old man was admitted to the hospital complaining of a right inguinal hernia of 6 weeks duration. He had experienced occasional dragging pain in the right groin, gas and sour eructations. Physical examination was not remarkable except for a right indirect inguinal hernia. Herniorrhaphy was performed, and convalescence was normal. After discharge from the hospital gaseous eructations and epigastric distress continued. The patient was studied in the Out Door Department and the stools were found to be strongly positive for occult blood. X-ray studies suggested carcinoma of the stomach. The patient was therefore readmitted, 5 months after herniorrhaphy for gastric resection for carcinoma. During the 2 month interval since gastric resection, he has had no gastrointestinal symptoms.

CASE 2 A 58 year old man was admitted to the hospital complaining of bilateral inguinal hernias of 3 years duration. These had been increasing in size prior to admission and were especially prominent when the patient strained at stool. The patient complained of chronic constipation, and had recently been taking increasing daily doses of laxatives. There were no groin symptoms, abdominal pain or weight loss. Physical examination showed bilateral inguinal hernias, for which bilateral herniorrhaphy was done. At the time of operation, a hard nodule was noted in the right hernial sac, which was removed for microscopic study. A metastatic carcinoma was reported which was thought to have arisen from the gastrointestinal tract. Following recovery from herniorrhaphy, a barium enema demonstrated an obstructive lesion of the sigmoid. Subsequently, at an abdominal exploration carcinoma of the sigmoid, with diffuse peritoneal metastases was discovered.

These 2 cases are but examples of the pitfalls hidden by apparently simple cases of inguinal hernia. Behind the mildest symptoms may lurk serious disorders detrimental to the patient's health. This is especially true in the middle aged and the elderly, since advancing years bring on an increased incidence of serious constitutional disease. Both urinary obstruction and chronic cough are well recognized contraindications to herniorrhaphy, and efforts are made to remedy or control these conditions previous to operation. The physician and patient, however, are only too willing to assume that the presenting inguinal hernia is the sole cause for the patient's indigestion and to proceed with herniorrhaphy without further investigation. We believe that ulcer in the younger age groups and gall bladder disease and cancer in the middle aged or the elderly must be carefully ex-

cluded in patients with inguinal hernia with gastrointestinal symptoms before the hernia is repaired.

Obviously, it is impractical and financially impossible to subject every patient with an inguinal hernia and gastrointestinal symptoms to complete roentgenologic examination, however desirable this may be. But there are simple methods that will narrow down the field until only a few remain who demand further investigation. A painstaking history with special reference to the nature of the gastrointestinal symptoms and their duration often indicates patients in whom ulcer, gall bladder disease or cancer is to be suspected. A thorough general physical examination is, of course, essential. Abdominal masses and tenderness should be sought. Rectal examination must be most thorough, and should include not only a careful evaluation of the size, shape and consistence of the prostate but also a search for masses suggestive of carcinoma in or about the rectum. Laboratory studies, including those of the blood, stool and urine, are indispensable. The finding of occult blood in a stool specimen, as illustrated in Case 1, may be the clue that abnormalities other than the hernia are present. If such measures fail completely to explain persistent gastrointestinal complaints, then the physician must carry out further investigation by x-ray.

CONCLUSIONS

Gastrointestinal symptoms occur in approximately one fifth of the patients with inguinal hernia. These symptoms, if well established, may indicate basic or antecedent causes other than hernia. The cause for such symptoms must be completely explained before operation for inguinal hernia is advised.

EMERGENCY MEDICAL SERVICE FOR A SMALL CITY

FREDERICK T. HILL, M.D.*

WATERVILLE, MAINE

IN the setting up of an emergency medical service for civilian defense, it seems decidedly advantageous to take into consideration the medical facilities and personnel that might be available. Frequently, the small community is confused, and perhaps overwhelmed, by stereotyped plans laid down by state and national authorities

more first-aid squads, and to establish first-aid posts near the scene of any incident. Stations are also prepared to handle minor cases not requiring hospitalization.

Each hospital was asked to appoint an executive medical officer, to be in charge of medical personnel, and an admitting officer, to be in charge of

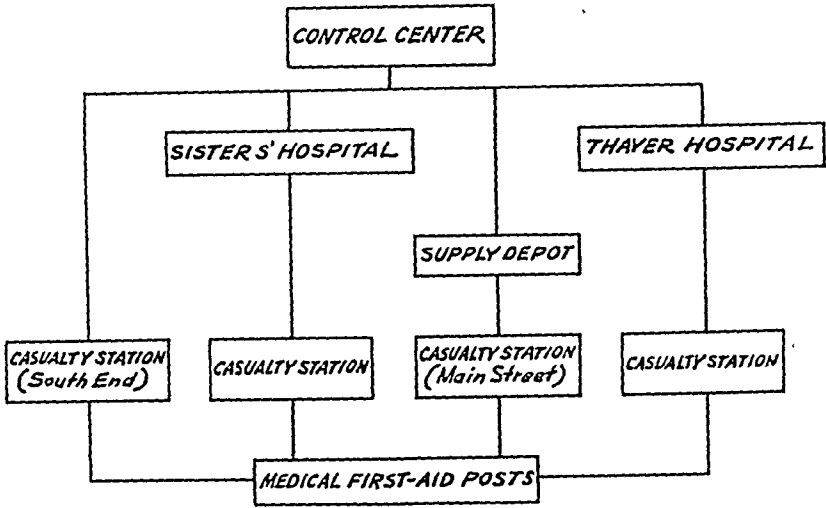

FIGURE 1.

—plans that might be possible of execution in a large city but are quite impractical for the smaller place. When one remembers the constantly diminishing supply of physicians, as more of the younger doctors are called into service, it becomes increasingly imperative that any emergency medical service be adapted to local conditions.

It was my lot to be drafted to reorganize such an emergency medical service in Waterville, Maine, a small city. The previous attempts to pattern the service on stereotyped plans had not been productive of satisfactory results.

The first step in the new plan was the utilization of the two hospitals in the city not only as casualty receiving hospitals but also as casualty stations and to furnish pools of physicians and nurses. In addition, two other casualty stations were set up to take care of sections not readily covered by the hospitals. A supply depot was established at the most centrally located casualty station.

Each casualty station, including the hospitals, is to be prepared to send out medical squads consisting of 1 physician, 1 or more nurses and 1 or

patients admitted because of an emergency. Provision was made for alternates. It was stated that these should be physicians of experience and executive ability, able to size up situations and make decisions quickly.

The executive medical officer specifies the duties of the physicians at his station, such as dressing room, shock room, fractures, burns and major surgery; naturally, these assignments will vary according to the type of admissions and the personnel available. He assigns physicians to be in charge of first-aid posts, when requests for such posts are received from the control center. He should exercise due judgment regarding the size and make-up of each squad, depending both on the information received of the extent of the incident and on his available supply of physicians. The executive medical officer should make a list of all physicians, nurses, first-aiders and so forth reporting at his station. This should be available for the medical service when the mobilization is over.

The admitting officer should be a physician of keen clinical judgment. He will examine cases on admission and assign them to the proper department.

*Chief of staff, Thayer Hospital; chief, Emergency Medical Service, Office of Civilian Defense.

Each hospital will be notified by the control center on the yellow signal and should then proceed to ask certain of its medical personnel to assemble before the red signal. On the blue signal, the control center will ask each hospital the number of available beds. On this signal, all physicians, nurses, first aiders and ambulances are requested to report to their stations. On the red signal, stations will telephone the control center, reporting the number of physicians, nurses and first aiders at their posts.

The chief medical officer, with an assistant to act as clerk, handles the service from the control center. Two other physicians are familiar with this phase of the work and will be able to take charge in his absence. In fact, all key positions in the service are covered "three deep."

Three physicians are assigned to each of the casualty stations. The staffs of the two hospitals cover their respective institutions, furnishing personnel for the casualty stations, first aid posts and the hospital itself. Graduate nurses and first aid squads are assigned to each of the four stations. Three ambulances are assigned to each hospital, and two to each of the other stations. One or more dentists are assigned to each of the hospitals and stations.

Since, in the event of an emergency, a great deal of difficulty and confusion may be caused by distracted and hysterical relatives and friends, members of the clergy—one Catholic priest and one Protestant clergyman—have been assigned to each of the stations. An emergency morgue, in charge of an official of the Police Department, and with a Catholic priest and Protestant clergyman assigned to it, has been set up in the Municipal Armory. The supply depot, in which the reserve medical and surgical supplies, reserve emergency chests and so forth are kept, is in charge of three lay persons who are experienced in this work and who are responsible for the medical equipment of the ambulances. A pool of extra ambulances is assigned to this supply depot. The supply depot has also been charged with the responsibility of maintaining an adequate supply of various drugs, such as tetanus antitoxin and so forth, at the casualty stations. Plasma in adequate amounts is kept in storage at the two hospitals.

Telephone service must be maintained at an efficient level. When an incident requiring medical service is reported to the control center, the chief medical officer will notify the most available casualty station. The telephone operator takes the message in writing, repeats the message to the center for check, and immediately transmits it to

the executive medical officer, who then dispatches one or more medical squads to the scene. As soon as this is done, the telephone operator notifies the control center as follows: "One (two) squad(s) to ——— St. at — p m."

On arrival of the squad at the incident, a first-aid post will be set up in the most convenient location, the main essentials being light, water and communications (telephone). The squad will call its own station (hospital) if additional personnel, supplies and so forth are required and, if possible, will notify the hospital if cases are to be sent in. The executive medical officer at the station will notify the control center if an additional squad is dispatched.

If any station (hospital) is unable to furnish needed personnel or supplies, or is being depleted by the sending out of squads, the executive officer should notify the chief medical officer at the control center, who will send personnel, supplies and so forth from other stations or the supply depot.

Tags will be filled out as much as is practical at the first-aid posts. Naturally, there should not be undue delay in sending very seriously injured persons to the hospital, and many data can be obtained later at the hospital. All emergency treatment given, such as the injection of morphine or the application of a tourniquet, should be noted by marking on the forehead. Urgent cases should be marked "U." Hospitals should keep records of all cases admitted in the casualty record books furnished for this purpose.

All personnel should remain at the stations until "cleared" by the chief medical officer at the control center.

Three mobilizations, with simulated incidents, are conducted each month, in addition to a series of meetings for the entire medical service at which pertinent problems, such as "first aid posts," "casualty stations," and "treatment of gas casualties," are discussed. It has become obvious that the main problem is one of coordination between the physician, the nurse and the first aid squad. The average physician knows little about setting up or handling a first aid post. He can take care of one casualty, but is quite at a loss when confronted with ten or twelve. Yet he is in charge and should be familiar with these problems. It is only by practice, constructively criticized, that this matter can be worked out efficiently. A system of observers—physicians competent in handling these situations—has been employed. These men not only criticize but also give instruction to the doctor, the nurse and the first aid squad.

The first aid organization is under the direction of a corps director and consists of five squads and

assigned to each station and one held in reserve. Each squad is commanded by a squad leader, who is a qualified instructor. Each squad consists of four units of four men under a unit leader, who holds a Red Cross advanced certificate. One unit of each squad functions at the station, making tag records, assisting nurses, preparing dressings and splints and taking charge of patients' clothes and personal effects. Two units are allocated to ambulance duty, and one unit is held in reserve. Definite duties are assigned to each unit member, such as responsibility for ambulance equipment and splints, and the members are trained to act as a unit in handling casualties. These squads are all under the command of the corps director, who is responsible for this training. We have been for-

tunate in having as a director a man who has had a long experience as an instructor in first aid at the mill of a paper company that has long been recognized for its efficiency in first-aid and safety work. The director has been able to bring with him as squad leaders men who have served under him as instructors. One such squad of trained first-aiders, working under a capable leader, is worth more than a large number of well-meaning but inexperienced amateurs.

So far this plan seems to be working out very well. It is not suggested as anything new or ideal, but as a means by which a small city with limited medical personnel can meet the emergency.

Professional Building

IS TUBERCULOSIS INCREASING?*

JOHN A. FOLEY, M.D.†

BOSTON

FOR several years, the opinion has been prevalent that tuberculosis is decreasing and that the fight against this disease has finally made definite headway. To those who are working in the field, however, there seems to be another view. At the Boston Sanatorium, the largest hospital devoted to the care of the tuberculous patient in Massachusetts, we have had an experience, over the past five years, that leads us to think that other factors have not been considered.

The total number of patients treated in 1936 was 1079; in 1937, 1088; in 1938, 1082; in 1939, 1042; in 1940, 1070; and in 1941, 1110. These patients came from two sources, the Boston Health Department and the Boston City Hospital. According to these figures, there has been a gradual increase in the admissions to the Sanatorium since 1939. The number of minimal cases consistently remained approximately 10 per cent up to 1939, when it decreased to 8 per cent; in 1940, it was 8 per cent and in 1941 7 per cent. Hence, as the total number of treated cases increased, the number of minimal cases decreased and the number of moderately advanced cases increased. This indicates either that the cases are not being discovered early enough or that the patients are not being sent for treatment until they are well along

in the disease. It is pertinent to say that the minimal cases are usually discovered by extensive studies on large groups or by the study of contacts of known cases, whereas the great majority of the moderately advanced cases are picked up as the result of hospitalization for other conditions, or as the result of neglect on the part of the patient to consult his physician in time. This is equally true of the far-advanced cases.

In 1941, 29 per cent of the patients with tuberculosis who died in Boston were not reported to the Health Department until after death, and 13 per cent were reported within a month before death; the disease should have been discovered early enough to ensure information to the Health Department. In short, in 13 per cent of the known deaths from tuberculosis, the patients had no health supervision, no checkup of contacts and no restriction of activity until a month before death, and 29 per cent had no supervision whatsoever. From what is known about this disease, these patients were potentially disseminators of the tubercle bacilli for a number of months before death. When this situation is appreciated, it is not difficult to understand why 55 to 60 per cent of the deaths in 1941 at the Boston Sanatorium occurred before the patients had been at the hospital six months; their cases were so far advanced that no treatment could avail. This was not unique for 1941; it has been the same story during the last five years.

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 26, 1942.
†Clinical professor of medicine, Boston University School of Medicine; director of Fifth and Sixth Medical Services, Boston City Hospital; chief of staff, Boston Sanatorium

This is not an isolated example of the belated discovery of tuberculosis. The May 16, 1942, issue of the *Journal of the American Medical Association* reports that of 594 men rejected for tuberculosis by the selective-service boards of Illinois, only 21 had previous records reported to the State Board of Health. At the Boston Sanatorium, 15 patients have been referred after having been rejected by their local selective-service or induction boards, few of whom suspected that they were infected. All this leads one to believe that tuberculosis will never decrease until the carriers are discovered and regulated. This will be accomplished for the male population, in a large measure, by the examinations preceding induction. This still leaves the female population to be studied; a number of these will fall into the contacts of diseased males and will be picked up in this way.

The main effort must be made with younger age groups, in the junior high schools and the secondary schools. This group should be tuberculin tested, and the reactors examined by x-ray and reported to the health authorities for follow-up. It is a simple matter for the family physician to apply a patch test, read it, and have a reactor x-rayed, but most men are reluctant to report the minimal case.

Hence, such patients who respond readily to a sanatorium regime are allowed to remain at home, where they are inadequately treated and soon become moderately or far advanced. When the problem becomes acute, they are sent to a sanatorium.

If tuberculosis is to be successfully combated, children must be patch tested, those who react must be x-rayed, and *all* cases of tuberculous infection must be reported.

464 Commonwealth Avenue

MEDICAL PROGRESS

THE BILE PIGMENTS*

CECIL J. WATSON, M.D.†

MINNEAPOLIS

THE problem of the bile pigments has always been intriguing to the clinician as well as to the physiologist, pathologist and chemist. It is quite impossible to consider this problem adequately from any one of these viewpoints. The present communication, therefore, will strive to present a survey of recent general progress in this field, with particular emphasis, however, on clinical applications, and with some attempt to correlate or compare the results of recent studies with those of the older literature, at least sufficiently for purposes of orientation. The allotted space does not permit any comprehensive review of the literature, or even an inclusion of all the various aspects of the problem. The topic of the bile pigments in relation to hemoglobin metabolism must necessarily be omitted in large part, and greater emphasis is placed on the relation of the bile pigments to jaundice and liver disease.

BILIRUBIN

For many years, it was generally held that the transition of hemoglobin to bilirubin was characterized by a primary splitting off of the protein globin, with resulting formation of hematin. The next step was thought to be the removal of iron, followed by an opening of the porphyrin ring to yield bilirubin. This belief was founded to some extent on the ease with which hematin is obtained in vitro from hemoglobin, as well as on the known occurrence of hematin, under certain circumstances, in vivo; there was also the old idea that the iron-free hematoporphyrin of Hoppe-Seyler was an isomer and probable precursor of bilirubin. The latter investigations of the Hans Fischer school revealed clearly that the underlying porphyrin in the hemoglobin molecule, and the one standing in closest relation to bilirubin, is not hematoporphyrin but protoporphyrin. All these earlier beliefs have been dealt with in a previous review,¹ and need not be considered in more detail. Within the past few years, new concepts of bile-pigment formation have been introduced

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress Annual*, Vol. III, 1942 (Springfield, Illinois: Charles C. Thomas Company, 1942. \$5.00).

*From the Division of Internal Medicine, University of Minnesota Hospital.

†Professor of internal medicine, University of Minnesota Medical School.

that are based on the much firmer ground of an *in vitro* method of conversion of hemoglobin to bilirubin without the aid of living cells. Although it remains to be proved that this method obtains *in vivo*, there can be no doubt that it is sufficiently simple and physiologic in type to be quite compatible with an *in vivo* mechanism.

Perhaps the first observation bearing on this new concept was that of Fischer and Lindner² in 1926. They observed that green compounds, assumed to be similar to bile pigments, were formed when yeast and hemoglobin were incubated together. Warburg and Negelein³ observed that when hemin is treated with pyridine-O₂-hydrazin hydrochloride a "green hemin" results. This was studied further by Lemberg et al.⁴ who identified it as a biliverdin-iron-globin compound. By means of a coupled oxidation of hemoglobin or hemin with ascorbic acid, Lemberg and his co-workers⁵⁻⁹ obtained bile-pigment-iron-protein compounds designated as "choleoglobin," "verdo-hematin" or "verdohemochromogen." The first crystalline bilirubin was prepared by the same general procedure by Fischer and Libowitzky,¹⁰ although in this study an artificial coprohemin was used and an analogous coprobilirubin was isolated. The results, nevertheless, are just as significant so far as the underlying principle is concerned. This method of preparing bilirubin from hemoglobin *in vitro* has been confirmed by others.¹¹⁻¹³ The intermediary green compound differs from hemoglobin or hemin, as the case may be, through an opening of the protoporphyrin ring by an oxidative removal of the α -methene bridge. There is some reason to believe that the iron must be present for the porphyrin ring to open, at least under natural conditions. Thus, the administration of iron-free protoporphyrin to dogs with biliary renal fistulas was not followed by an increased excretion of bilirubin.¹⁴

It is probable that the so-called "pseudohemoglobin" of Barkan¹⁵ is closely related to Lemberg's verdohemoglobin. (As prepared *in vitro* by the action of hydrogen peroxide, the compound obtained, according to Lemberg,⁶ is actually a ferrous denatured globin-cyancholehemochromogen.) Barkan has shown that the iron of the pseudohemoglobin is "easily split off" by dilute hydrochloric acid, whereas that of ordinary hemoglobin is unaffected. The presence of a certain amount of easily-split-off iron in the hemoglobin of normally circulating erythrocytes indicates that at least a fraction of this hemoglobin is of the pseudohemoglobin or verdohemoglobin type.⁹ Barkan^{15, 16} has further shown that sterile incubation of erythrocytes for six hours is followed by an increase of

iron and bilirubin in the supernatant plasma, as well as pseudohemoglobin in the red cells. All this indicates an intracorpuseular degradation of hemoglobin. The magnitude of the total wastage of hemoglobin is unknown. Recent studies by Watson and Paine¹⁷ have shown that the erythrocytes sequestered in the splenic pulp and thrown into the splenic vein after adrenalin is administered, particularly in cases of hemolytic jaundice, are comparatively poor in hemoglobin. This reduction in hemoglobin concentration was unexplained except on the basis of intracorpuseular degradation during the period that the cells were in the spleen. The associated increased spheroidocytosis and increased fragility of the splenic-vein erythrocytes, noted after adrenalin, may be fundamentally correlated phenomena. Thus, Fahreus¹⁸ has shown that stasis of red cells in the spleen, or *in vitro*, results in increased spheroidicity, which he believes to be due to formation of lysolecithin as a result of the change in the interface relation between the red cells and the plasma. It is quite possible that all these phenomena are correlated with a reduction of catalase in the erythrocytes, which Engel^{12, 13} has shown to be of importance in retarding the conversion of hemoglobin to verdohemoglobin. Under ordinary circumstances, free hemoglobin in the plasma is quickly converted to bilirubin,¹ so that it is quite obvious that a relatively high degree of protection from oxidation obtains within the cells. Whether this is entirely due to catalase or not is unknown. This question is referred to below in the consideration of "pentdyopent."

In the conversion of hemoglobin to bilirubin, the fate of the globin is quite unknown. Duesberg^{19, 20} suggested that the globin is never separated and that the plasma bilirubin is in fact a bilirubinglobin. This possibility will be returned to shortly. It may be noted first that Duesberg's belief was based on his own and Bingold's²¹ observations that hematin, quite in contrast with hemoglobin, did not appear to be converted into bilirubin *in vivo*. A series of experiments* carried out in this laboratory have failed to confirm this belief and in fact have provided abundant evidence that the conversion of hematin to bilirubin is just as quantitative as that of hemoglobin.

Studies of the nature of the direct and indirect van den Bergh reactions have recently thrown much light on the general problem of bilirubin and the serum proteins. The earlier view that the indirect reacting bilirubin was attached to the serum globulin²² has been shown to be incorrect.

*Watson, C. J. *Proc. 1*], and Schwartz, S. Unpublished data.

The studies of Bennhold,²³ Pedersen and Waldenstrom⁴ and Coolidge²⁰ clearly reveal that both direct and indirect types are bound to the serum albumin. Bennhold²³ points out that if it were not for the attachment of bilirubin to the serum albumin, jaundice would undoubtedly be more intense than it is, since the concentration of bilirubin is regularly higher in the serum than in the tissues. The indirect reacting bilirubin, according to Coolidge,²⁰ is chemically bound (with valence bonds), whereas the prompt, direct reacting type is simply absorbed loosely.

If Duesberg's¹⁹⁻²⁰ hypothesis is correct, it follows that globin is closely akin to, if not identical with, serum albumin. Pedersen and Waldenstrom²¹ emphasize the close physical similarity, the main difference being in the isoelectric point of hemoglobin (pH, 7.0) and serum albumin (pH, 4.8). The two proteins have identical molecular weights and they are not separable in the ultracentrifuge.²⁴ It is at least obvious, at this stage of our knowledge of the problem, that the globin could well remain attached throughout the transition of hemoglobin to bilirubin, and could then be incorporated in the serum albumin fraction, still attached to bilirubin. In fact, this appears to be much more reasonable than to assume that the bilirubin and globin are separated only to have the bilirubin reattach itself to another and very similar protein. Here again, it is evident that further investigation is needed.

From the foregoing statements, it should not be assumed that the different mechanism of the indirect, as compared with the prompt direct van den Bergh reaction, has been proved to depend on the type of attachment to serum albumin. It appears that this is important, but it remains to be shown that purely chemical differences in the bilirubin molecule are not also of significance. The question of furan ring formation, as suggested by Fowweather,²⁵ was considered at some length in an earlier review.¹ The most recent studies of the Fischer²⁷ school indicate the presence of a furan ring in the molecule. Davis and Sheard²⁸ have shown that a distinct difference exists in the ultraviolet absorption spectra of the prompt direct and the indirect reacting types of bilirubin. Previous studies had indicated another physicochemical difference between the two types—that is, a difference in filtrability through semipermeable membranes. Recent studies by Gregory and Andersch²⁹ failed to confirm this supposed difference. Snapper and Bendien³⁰ have shown, however, that *in vitro* studies of the ultrafiltrability of bilirubin are rendered difficult of interpretation because of a number of variable experimental factors. Heilbrun and Hubbard³¹ have recently called attention again to

the chloroform solubility of the indirect reacting bilirubin in the serum. They recommend simple repeated extractions of the serum with chloroform, which is separated by centrifuging and is then compared with a standard potassium bichromate solution. This appears to be a useful procedure, especially when a photoelectric colorimeter is not available for employment of the Malloy-Evelyn³² method.

Another interesting theory regarding the basis of the different diazo reactions has been suggested by Colanguih,³³ mesobilirubin is responsible for the delayed or indirect reaction, bilirubin only for the prompt direct. This assumption merits further study. Mesobilirubin is intermediary between bilirubin and mesobilirubinogen, the latter being one of the urobilinogens. Mesobilirubin is lighter in color than bilirubin (yellow rather than orange) but in other respects behaves like it, giving the Gmelin color play with yellow nitric acid, as well as the diazo reaction, but not Ehrlich's aldehyde test. The occurrence of mesobilirubin in nature has not yet been proved. It is readily prepared from bilirubin by suitable reduction, and it is entirely conceivable that bilirubin might be reduced in part either in the blood stream or in the organs with resultant mesobilirubin formation. It has been shown, for example, that crystalline stercobilin injected intravenously is often reduced in part to stercobilinogen.¹

The determination of serum bilirubin has become much simpler and more accurate because of the adaptation of the van den Bergh method to the Evelyn photoelectric colorimeter. The procedure described by Malloy and Evelyn³² permits ready distinction of the direct and indirect reacting serum bilirubin. Unfortunately, however, they recommend reading the total direct reacting bilirubin only after thirty minutes. This, of course, combines the prompt and delayed types, which have entirely different significance. In the laboratory of the University of Minnesota Hospital, it has been customary for some time to take readings at one minute and again at fifteen minutes, the first being the prompt reacting bilirubin and the second the delayed type. The total is then determined by the Malloy-Evelyn method, the difference between this and the amount observed at fifteen minutes constituting the indirect fraction. The original van den Bergh method and many subsequent modifications of it undoubtedly gave low values for total bilirubin because of some loss on the protein precipitated by the alcohol. Malloy and Evelyn³² found that the indirect reaction was just as complete with 50 per cent or even lower concentrations of alcohol and that the serum pro

teins were not precipitated at this concentration if the serum was first diluted. The sensitivity of the Evelyn colorimeter is quite sufficient to permit this dilution.

The bilirubin tolerance test of liver function, as originally described by von Bergmann and Eilbott, was the subject of a critical study by Strasser,³⁴ who concluded that the method affords a very delicate means of testing the bilirubin excretory function of the liver in nonjaundiced persons. More recently, Weech and his associates³⁵ have suggested a bilirubin clearance test applicable as well to jaundiced patients, the rate of removal being evaluated as a velocity constant of excretion, a measure that these investigators believe to be unaffected by elevation of the basal plasma bilirubin concentration.

BILIRUBIN DERIVATIVES OF CLINICAL IMPORTANCE

Biliverdin

This substance, also known as dehydrobilirubin because it is formed by dehydrogenation of bilirubin, comprises the pigment fraction of verdohemoglobin, as noted above. There is no reason to believe, however, that biliverdin as such is contributed to the serum from destroyed hemoglobin. If this were true, accumulation of biliverdin—in other words “biliverdin icterus”—might be expected in cases of retention jaundice, especially those of hemolytic type. The occurrence of biliverdin in the serum has been studied recently in this laboratory.* With the Evelyn photoelectric colorimeter, the serum biliverdin is readily determined by virtue of its relatively strong absorption in the red portion of the spectrum. This study is not completed, but the results so far obtained indicate that biliverdin does not accumulate in pure retention jaundice. In regurgitation jaundice, whatever the cause, some biliverdin has been noted regularly. Except in jaundice due to cancer, however, the serum biliverdin has not exceeded 1.0 mg. per 100 cc., in accord with the observation that outspoken biliverdin jaundice is most frequently due to cancer of the biliary tract.³⁶ A few marked exceptions have been noted in which the jaundice was of parenchymal type (subacute or prolonged hepatitis or cirrhosis).

A “green reaction” with Ehrlich’s test for urobilinogen in the urine is encountered in some patients with marked bilirubinuria. This has been shown to be due to biliverdin formed by the action of sufficiently high nitrite concentration in the urine, and stabilized at the biliverdin stage by the *p*-dimethylaminobenzaldehyde of the reagent.³⁷

Urobilinogens and Related Compounds

Historical facts. In a consideration of recent advances in the study of this group, it is desirable for purposes of orientation to refer briefly to some of the earlier literature. The term “urobilin” was first employed by Jaffe³⁸ in 1866 to describe an orange pigment, which he observed both in bile and in certain urines. Jaffe noted that this substance exhibited intense green fluorescence with zinc chloride and ammonia, as well as a strong absorption band in the region of 500 millimicrons. In 1871, Vanlair and Masius³⁹ found an entirely similar pigment in the feces. With appropriate caution, since they were uncertain of its identity with Jaffe’s urobilin, they designated the fecal pigment as stercobilin. The description of these substances was confirmed, in the main, by MacMunn⁴⁰ in 1878. It must be noted, however, that MacMunn described a distinct, although slight, difference in position of the absorption band of the urobilin from bile as compared with that from urine. In 1901, Ehrlich⁴¹ described a color reaction in the urine with concentrated hydrochloric acid and *p*-dimethylaminobenzaldehyde. Although he was ignorant of the substance giving this reaction, he was aware that it was relatively common in cases of liver disease and in certain anemias. Neubauer⁴² was the first to show that the reaction was due to the presence of a chromogen of Jaffe’s urobilin. This chromogen was further studied by le Nobel,⁴³ who named it “urobilinogen.” As early as 1887, Friedrich von Müller⁴⁴ had shown that the formation of urobilin and its occurrence in the urine were dependent on the presence of bile in the intestinal tract, thus demonstrating simultaneously the enterogenous origin of urobilin and its enterohepatic circulation. This work was confirmed many years later by the extensive studies of McMaster and Elman.⁴⁵ The first concrete knowledge of the chemistry of this group of substances was provided by Fischer⁴⁶ in 1911. He reduced bilirubin with amalgam, and then isolated the resulting chromogen in crystalline form.⁴⁶ This was first designated as “hemibilirubin,” since the yield was less than 50 per cent and it was thought that but half the bilirubin molecule had been converted into the crystalline chromogen. In the same year, the substance was isolated from urines rich in urobilinogen (strong Ehrlich reaction).⁴⁷ By 1914, Fischer⁴⁸ had shown that mesobilirubin was intermediary and that there was no evidence that half the bilirubin molecule was converted to some other compound during the reduction. The chromogen was therefore renamed “mesobilirubinogen.” On exposure to light and air, this substance develops urobilin characteristics, and the Ehrlich

reaction gradually disappears. The transition can be hastened by mild oxidizing agents, such as iodine. This was employed by Schlesinger,⁴⁹ together with alcoholic zinc acetate, in what has become the best known qualitative test for urobilin (not urobilinogen).

Recent fundamental advances. For a number of years after the studies of the Fischer school, the question whether mesobilirubinogen was the sole urobilinogen remained unanswered. Was the stercobilin of the feces identical with the urobilin derived in vitro from mesobilirubinogen? Prior to 1932, many attempts^{46, 50-52} to answer this question by isolating either chromogen or pigment from the feces had failed. In 1932, crystalline stercobilin was isolated from human feces.^{53, 54} The same substance was obtained from pathologic human urines in 1933.^{55, 56} A method was then devised for preparing crystalline urobilin from mesobilirubinogen, and it was shown that this urobilin differed in a number of respects from stercobilin.^{57, 58} This was confirmed by Fischer and his co-workers.⁵⁹⁻⁶¹ Siedel and Meier⁶¹ synthesized this compound and designated it as urobilin IX *a*, indicating simply that the configuration corresponds with that of the protoporphyrin in the hemoglobin molecule—that is, Type IX of the fifteen possible isomers—and also that the porphyrin ring has opened at the α -methene bridge. Fischer and his associates⁵⁹ found that although urobilin IX *a* is optically inactive, stercobilin is strongly levorotatory. This will be referred to again in the following. They also noted that the melting points of the free substances were distinctive when recrystallized from acetone.^{60, 61} Shortly after the isolation of stercobilin, attempts were made to reduce it and isolate the chromogen to determine whether or not this was mesobilirubinogen. The reduction is easily carried out, but the resulting chromogen (stercobilinogen) has not yet been crystallized, although mesobilirubinogen crystallizes readily in much smaller amounts under the same conditions. Recent studies have to some extent clarified the nature of stercobilin and its relation to mesobilirubinogen.

The possibility that there were two bilirubins in the bile—one on reduction in the intestinal tract yielding mesobilirubinogen and the other stercobilinogen—was first considered. It was quite conceivable, for example, that some of the porphyrin of the hemoglobin molecule might open its ring, not at the α -methene bridge, but at one of the other three. This, of course, would result in the formation of a different bilirubin, or a bilirubinoid substance. With this in mind, a number of human bile samples were reduced directly with

amalgam, until the Ehrlich reaction had become strong.⁶² The resulting urobilinogen, after partial purification, was converted to urobilin, which was then isolated. In every sample, this was urobilin IX *a* on the basis of optical activity, absorption spectrum and melting points. Stercobilin was never formed in this way, although it was occasionally native* in the bile, in which event it was first removed. This study revealed conclusively that the formation of stercobilin is dependent on a more complex sequence of events than the simple reduction of the bilirubin present in the bile. Lemberg⁶³ recently recommended that the term "stercobilin" be abandoned, but in view of these findings and other observations, which will be mentioned, it appears that the term is more descriptive than any other, since it is now certain that stercobilin formation is dependent on a peculiar chemical activity in the intestinal tract, probably related intimately to bacterial metabolism in the colon.

Experiments were next carried out with the specific purpose of determining whether stercobilin is derived from mesobilirubinogen. The possibility existed, of course, that it might be an offshoot from any of the intermediary reduction compounds in the pathway from bilirubin to mesobilirubinogen, such as mesobilirubin and dihydromesobilirubin. It was found that if crystalline mesobilirubinogen was given by mouth this was followed by an increased output of stercobilin in the feces.⁶⁴ Incubation of mesobilirubinogen with normal feces resulted in a clear-cut increase of stercobilin.⁶⁴ This was not true, however, of strictly acholic feces, in which mesobilirubinogen was unchanged. The addition of bile to such samples caused stercobilin formation in some, whereas a type of urobilin that is regularly observed in infected bile samples appeared in others. This new or third urobilin, as described by Schwartz and Watson,⁶⁵ is of particular interest in that it is dextrorotatory in the same magnitude that stercobilin is levorotatory. The melting point is the same as that of stercobilin, but the absorption is identical with that of urobilin IX *a*. The first two characteristics suggest that δ -urobilin, as this substance has been designated tentatively, may be a stereoisomer of stercobilin. Further studies of this question are planned. Dextro-urobilin is further characterized by a color play with dioxan hydrochloric acid.⁶⁵ A slight difference in the absorption maximums of urobilin IX *a* and stercobilin was first reported by Lemberg,⁶⁶ although the former had not at that time been crystallized or identified as

*The presence of stercobilin in the bile may be ascribed without doubt to the enterohepatic circulation. Crystalline stercobilin, when injected intravenously, reappears in the bile unchanged.

a distinct entity. Dextro-urobilin may usually be obtained from infected human fistula bile, although the yields are small owing to the difficulty of purification. Schwartz, Sborov and Watson⁶⁷ have further noted that mesobilirubinogen added to such infected samples is at least partially converted to *d*-urobilin. The significance of this change, as compared with that to stercobilin in normal feces, is as yet unknown. The above-mentioned experiments with acholic feces, bile and mesobilirubinogen, in which on one occasion stercobilin and on another *d*-urobilin were formed, indicate that some unknown factor influences the direction of the conversion. It is also un-

known whether there is a separate chromogen for *d*-urobilin as there certainly is for stercobilin, or whether mesobilirubinogen, under proper conditions, is converted directly to the dextrorotatory compound. As yet, no clinical importance has attached to this substance. It is quite conceivable that it will be found in the urine in biliary-tract infections, since it is well known that urobilin may be formed in the infected biliary tract.⁴⁵ It would also be of interest to investigate the bile obtained by duodenal drainage, with respect to the presence of *d*-urobilin. There can now be little doubt that the slight spectroscopic difference recorded for bile urobilin by MacMunn,⁴⁰ in 1878, was due to the presence of *d*-urobilin.

Thus, the quantitative determination of urobilinogen in the urine and feces includes any or all of the chromogens present in the sample. It has been shown repeatedly that both stercobilinogen and mesobilirubinogen occur in the feces and urine.¹ There is no evidence at present that either of these substances has a different clinical significance

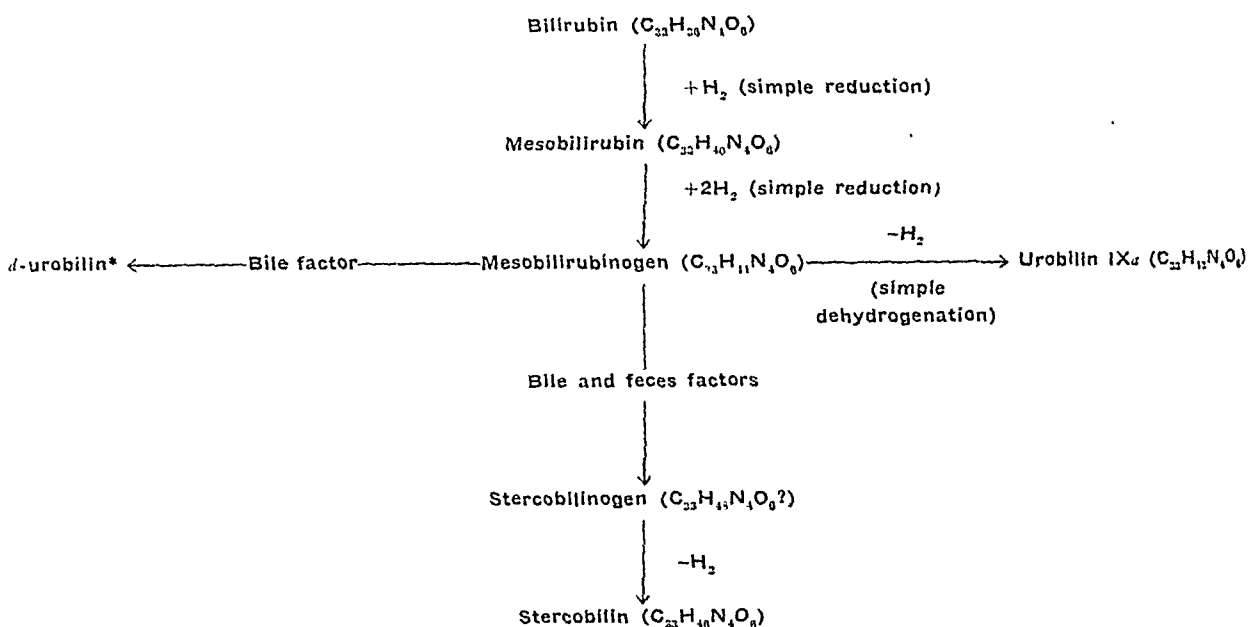

FIGURE 1.

known whether there is a separate chromogen for *d*-urobilin as there certainly is for stercobilin, or whether mesobilirubinogen, under proper conditions, is converted directly to the dextrorotatory compound. As yet, no clinical importance has attached to this substance. It is quite conceivable that it will be found in the urine in biliary-tract infections, since it is well known that urobilin may be formed in the infected biliary tract.⁴⁵ It would also be of interest to investigate the bile obtained by duodenal drainage, with respect to the presence of *d*-urobilin. There can now be little doubt that the slight spectroscopic difference recorded for bile urobilin by MacMunn,⁴⁰ in 1878, was due to the presence of *d*-urobilin.

As a result of these studies, it is evident that urobilinogen as tested for by the Ehrlich reaction

*As yet there have been no elementary analyses of this substance, so that the empirical formula is unknown.

from the other. Lemberg⁶⁸ suggested such a possibility on the basis of a differential test for stercobilin and urobilin IX *a* that was applicable to urine extracts. He found that heating with iron chloride and hydrochloric acid produced a violet reaction with urobilin IX *a*, whereas stercobilin was unchanged. When this method was applied to urine samples from various diseases, stercobilin was regularly found, and urobilin IX *a* but rarely. Lemberg therefore suggested that the latter might be pathologic. On the other hand, mesobilirubinogen (the precursor of urobilin IX *a*) has been isolated from the urine in considerable amount in widely divergent conditions, such as hepatic cirrhosis and other diseases,^{46, 48} including hemolytic jaundice.⁶⁸ In hemolytic jaundice, stercobilin was obtained from the mother liquor in an amount of the same magnitude as that of the mesobilirubinogen. NEW HAMPSHIRE MEDICAL SOCIETY

. PROCEEDINGS OF THE ONE HUNDRED AND FIFTY-FIRST ANNUAL MEETING

May 12 and 13, 1942

TUESDAY, MAY 12

THE scientific session of the New Hampshire Medical Society was opened at the Hotel Carpenter, Manchester, at eleven-thirty o'clock in the morning, with President Charles H. Dolloff presiding.

Dr. Deering G. Smith made the following remarks on the Procurement and Assignment Service.

I want to thank the members of the Society, especially the members of the county and state Medical Preparedness and Procurement and Assignment Committee, for the excellent work they have been doing. I expect that this co-operation and work will continue.

The Procurement and Assignment Service has been established to decide which doctors will go into the Army or Navy and which doctors will be considered essential for the care of the civilian population. In other words, at the same time the Army needs are taken care of, sufficient doctors must be kept at home to take care of civilian needs.

It has been stated that the Selective Service System is the dogcatcher, and the Procurement and Assignment Service is the Society for the Prevention of Cruelty to Animals.

In this state, the organization is headed by myself, as chairman; serving on the committee are Drs. Jones, of Manchester, and Bowler, of Hanover. In each county, there is a similar committee to advise the state committee.

Medical-enrollment forms have been sent to each doctor, and should be filled out and returned to the proper authority at once. If any of the doctors have not received these blanks, I shall be glad to furnish one.

Most of the doctors in the state have been classified as 3A under the Selective Service System. General Bowen, head of the Selective Service System in New Hampshire, has received instructions, which he is sending to the local boards today or tomorrow, notifying them to reclassify the doctors who are now in 3A. In the reclassification, the amount these doctors will receive as commissioned officers in the Army and Navy will be considered in figuring out whether or not they have dependents in sufficient number so that they will have to stay at home, rather than go into the Army.

The belief is that practically every doctor will be reclassified from 3A to 1A. He will be given a reasonable

time to apply for a commission in the Army if he is not considered essential, and will then, if he does not apply for a commission, be inducted as a private.

The need for medical officers is 15,000 more in 1942, and 5000 before July 1. That breaks down to 50 the number of medical officers needed in New Hampshire before July 1. To assist in the securing of this quota, the National Recruiting Board has established a medical recruiting board in New Hampshire. That is headed by Captain Weimars, of the Medical Corps. It gives me pleasure to introduce Captain Weimars.

Captain Weimars spoke as follows:

The Medical Officers' Recruiting Board will probably be located at 77 Main Street, Nashua. The purpose of this organization, as Dr. Smith has pointed out, is to get medical officers for the Army. He has told you how many are needed—about 5000 from the United States to be obtained before July 1. And, of course, an applicant must be physically fit before he can be given a commission.

We have the authority to cut the red tape, or at least to make it as light as possible, to get medical officers into the Army. We have the authority to act for the Surgeon General. We have the authority to disqualify or qualify physically any applicant for medical duty.

If you have been reading the *Journal of the American Medical Association*, you will have noted that the physical qualifications for medical officers have been considerably reduced. We have now what is termed a limited service. The limited service covers everything but field duty. Probably, such men will not see foreign duty. Thus, we can waive certain physical defects, such as missing teeth, an insufficient number of teeth, carious teeth and other minor defects.

An applicant must be a licensed practitioner of the State, must have had one year's internship, must be a citizen of the United States, and must be between the ages of twenty-six and forty-five. We can offer commissions to any person under thirty-seven to rank as a first lieutenant. We are authorized to recruit and commission applicants as first lieutenants, unless they have special qualifications, are members of a specialty Board or fellows of the American College of Surgeons or the American College of Physicians.

However, we have the authority, if applicants over thirty-seven and under forty-five meet certain qualifications, to commission them as captains.

A first lieutenant, unmarried and without dependents, gets approximately \$2700 a year. A first lieutenant, married, or having dependents, gets approximately \$3100 a year. A captain, unmarried, gets \$3300 a year, and a captain, married, gets \$3800 a year.

We have on our medical recruiting board a member from the Office of the Adjutant General who has the authority to swear in an applicant and give him his commission, serial number and rank and have him ready for active duty within a very short time. Accordingly, I present to you Lieutenant Veagle.

Lieutenant Veagle spoke as follows:

The Army needs medical officers. That is naturally true because a good many of your fellow citizens have been taken into the armed forces; consequently, some of you will have to go along with them to help protect them and keep them in good health and bring them back again. This program is being speeded up. Heretofore to obtain a commission, it took weeks and months and a good deal of red tape, the necessary papers were incomplete or lost here and there in Washington. When we once start to operate, a physician probably will be able to obtain a commission within a week at the most. Of course you will be allowed fourteen days after you receive your commission, or are sworn in, and under certain conditions you will be allowed a greater length of time. If you wish to waive the fourteen days and immediately go on duty undoubtedly we can find an assignment for you within a few hours.

Dr Metcalf read the following letter from the Bureau of Narcotics at Boston:

I deem it necessary to bring to the attention of the officers of the New Hampshire Medical Society information that should be disseminated for the protection of its members.

About this time of year, numerous carnivals, circus companies and outdoor shows start their season and visit various cities and towns throughout the State. This bureau has learned from experience that some of the personnel of these groups and their followers are frequently drug addicts. To obtain narcotics for the satisfaction of their addiction, these persons approach physicians in the towns where they are appearing, usually with a convincing story of an ailment that requires morphine for relief or even a story that they are on the way to a sanatorium for treatment and need a certain amount to tide them over. Physicians cannot be too careful about being prevailed on by these people, who have no medical need for narcotics.

I strongly urge the members of your society to be on their guard against the danger of being imposed on by such addicts. Unfortunately, the New Hampshire state law is inadequate in its provisions for prosecution of addicts who obtain narcotics, for the satisfaction of their addiction, under pretense, and the federal law has no punishment for the addict. However, under the federal law, any physician who prescribes or dispenses drugs indiscriminately, other than for an established medical need, is subject to prosecution for violation of the Harrison Narcotic Act, as amended. Every physician is required to determine, from a personal examination of a patient, that patient's medical need for narcotic drugs before prescribing or dispensing same. A physician should never accept the word of a patient that he has a certain physical ailment and requires narcotics for relief, or that a physician in another city has been giving him prescriptions for a

certain amount. You are cautioned to exercise extreme care to prescribe and dispense narcotics in the course of your professional practice only, and to patients under your care whose medical need has been definitely established by yourself.

In these days when careful conservation of the supply of narcotic drugs on hand is necessary because of world conditions, the Bureau of Narcotics is confident that the medical profession will co-operate wholeheartedly to prevent any diversion of these drugs to illegitimate channels.

WM E CLARK, District Supervisor

The morning session was concluded with an address by Dr Paul D White, of Boston, who opened the symposium on heart disease with a paper entitled 'Important Clues in Cardiovascular Diagnosis.'

The afternoon session convened at two o'clock with President Dolloff presiding.

Dr Ashton Graybiel, of Boston, continued the symposium on heart disease with a paper, entitled 'Electrocardiography.' Dr Richard Schatzki, of Boston, concluded the symposium with an address, 'Cardiovascular X-ray.'

Dr Bertrice M Kesten, of New York City, then presented a paper, entitled 'Dermatology.' The afternoon session was concluded with a talking, motion picture film in color, entitled 'Sex Hormones: Physiology, diagnosis and therapy,' which was presented by Parke, Davis and Company.

WEDNESDAY, MAY 13

The morning session convened at eleven fifteen o'clock, with President Dolloff presiding.

The following remarks were made by the visiting delegates from other New England state medical societies:

DR CARL E RICHARDS, Alfred, Maine. It gives me great pleasure to be able to attend this annual meeting of the New Hampshire Medical Society, and to be able to extend the greetings of the Maine Medical Association to you. I have enjoyed the meeting very much up to this point and I think the papers and discussion groups have been above par.

Being a general practitioner, I was particularly impressed with the papers presented yesterday in the symposium on heart disease and the paper on dermatology by Dr Kesten.

I am looking forward to hearing the papers by Drs Irons, Adair and Barker, and also to the banquet tonight, which I believe is a standing event.

The annual meeting of the Maine Medical Association will be held at the Poland Spring House, Poland Spring, Maine, on June 21, 22 and 23, and I have been asked by the president of the association to extend an invitation to the members of the New Hampshire Medical Society. The way things are with gasoline and tires and the like, we believe that this may be one of our last large meetings for the duration and an outstanding program has therefore been arranged, which will be brought to a conclusion by the appearance of Dr Morris Fishbein at the annual banquet on Tuesday evening, June 23.

DR. BERTRAND F. ANDREWS, Middlebury, Vermont: I was able to attend your meeting only today, so that I have not been here throughout the whole meeting. However, I am very glad to be able to be here with you and to bring you the greetings of the Vermont State Medical Society.

DR. C. BERTRAM GAY, Fitchburg, Massachusetts: I am very glad to be with you, and to bring the greetings of the Massachusetts Medical Society, as well as greetings from our president, Dr. Ober.

I came in a little while ago, and I see that you have a very interesting gathering here. Earlier this morning, I attended the Surgical Section, and heard a good discussion of gall-bladder disease.

We invite you to be with us at our annual meeting in Boston at the Hotel Statler in two weeks.

DR. JOHN J. CURLEY, Leominster, Massachusetts: I think that Dr. Gay has expressed the thoughts of the Massachusetts Medical Society very well.

DR. PAUL R. FELT, Middletown, Connecticut: By way of a long-continued and friendly tradition, I extend to you the greetings of the Connecticut State Medical Society. I can even say that after an abominable bus ride from Middletown to Manchester! We cordially invite all of you to the annual meeting of the Connecticut State Medical Society in Middletown the first week in June—I am not exactly sure of the dates at the moment. Our meetings will be held on the campus of Wesleyan University, and we are planning a very enjoyable time and shall be glad to see you there.

Dr. Ernest E. Irons, secretary of the Board of Trustees of the American Medical Association, presented the first paper of the morning, entitled "Aspiration Pneumonia." This concluded the morning session.

The afternoon session convened at two o'clock, with President Dolloff presiding.

Dr. Zatae L. Straw, of Manchester, was awarded a fifty-year-membership gold medal, and spoke as follows:

I thank you very sincerely for this signal honor, which you have conferred on me today in giving me this medal as a token of fifty years of busy, interesting and, I hope, worthy service in the practice of medicine in New Hampshire.

Of course, my being here is due to two factors only. One is the magnificent health I inherited from a long line of stalwart ancestors; the other is a determined and, I might say, congenital vocation to study medicine, because in my immediate family there were for years eight practicing doctors, although at present there are only five in three different states—New Jersey, Pennsylvania and New Hampshire.

I know the secret of popular public speaking. This is the recipe, which I intend to follow: be brief; be sincere; be seated. I shall not detain you for more than a moment, nor am I going to subject you to any résumé of the wonderful progress in the medical field during these fifty years. But I must refer, briefly, to the fact that, when I began to practice, we did not have sulfanilamide or the wonderful group of derivatives in that family. We did not know anything about insulin, through which years of comfort and active life are added to an otherwise hopeless outlook, or plastic and orthopedic

surgery and the wonder-working feats that are performed today, through which mangled and hopeless wrecks of humanity are transformed into active citizens. We had none of the modern anesthetists and the agents that they work with. We had practically no antiseptics or asepsis to speak of, as compared with what we have today. We knew nothing about blood transfusions or serum therapy. We did not know much of anything, some of you younger chaps will think, but we got along, and sometimes our patients got well. We are grateful. Once in a while they paid us, and that was a help, too, even then. If they did, it was all right, because that old doctor was not only the physician but also the legal adviser and minister and friend and moneylender and a good neighbor in every sense of the word.

Nowadays, we have no time for that. But that is the way it used to be.

We hope for much better things. However, in the next fifty years, I cannot possibly foresee such great progress in this or any other field as we have experienced in the last fifty years.

It has been a great treat, a great boon, to have lived in these fifty years, and I doubt if the next hundred years will hold as much interest and progress in any line.

Fifty years ago, the woman doctor was an unknown quantity, more or less, a rare species. They hardly knew how to take us. But, I joined the medical society, and since that time I have been accepted and treated just like one of you, and that is precisely as I wanted to have it. I have had a square deal in every way, and I want to express my appreciation and gratitude to the boys in Manchester, to my associates in the medical profession in Manchester, for their unvarying courtesy and friendly, professional consideration during all these years.

Another fifty-year-membership gold medal was awarded to Dr. Edwin P. Hodgdon, of Lakeport, who spoke as follows:

I thank the members of the New Hampshire Medical Society for this wonderful emblem. I never really expected to receive one, because twenty-five years ago, I was refused life insurance by a well-known company because of my family history and also because of a large abdominal girth. However, I served notice on the Chief Medical Examiner that I would be present at his funeral!

There is an old saying that the first fifty years are the hardest, but I want to rebut that statement: I can truthfully say that the first fifty years have been grateful ones to me. In the "Gay Nineties" I think I enjoyed myself as much or more than I have in the following years. We did not have tire or gasoline troubles. The only thing we had to find out was the price of plain oats.

Dr. H. O. Smith then made the following remarks:

In September, 1859, a baby boy appeared in the town of Milford, and his parents burdened him with the long name of Herbert Stillman Hutchinson. The boy waxed in stature and in wisdom. In due time, he entered Dartmouth. He graduated from Dartmouth in the year 1875, sixty-five long years ago. Today, he is the oldest in the list of living Dartmouth graduates.

After graduation, he began the study of medicine. He went to Bellevue Hospital Medical College, which did itself honor by giving him the degree of M.D. in 1880.

After his graduation, he returned to his home town of Milford, and he has been practicing medicine there ever

since. He is known and loved by every man, woman and child in that town.

Ten years ago, we gave Dr. Hutchinson a gold medal representing his fifty years of membership in the Society. Today, he has attained the rare distinction of having been a member for sixty years.

Mr. President and members of the Society, I deem it a great honor and a great privilege to present to you Dr. Herbert Sullman Hutchinson, our sixty year member.

Dr. Hutchinson spoke as follows

It was a considerable surprise to me when I was asked to be here today. I had supposed that my presence was no longer needed.

The two members of the Society who have preceded me and I belong to what is known as the horse and buggy days and that means more to us, perhaps, than to those who have gone into the service more recently, bad roads, and more nightwork than is now indulged in. It meant muddy roads and ruts, spring and fall, and deep snows and unbroken roads in the wintertime. It meant everything that was exhausting to a person, if he so willed to take up the duties that he was called on to perform.

Since then, many things have happened. Many have passed on. The country doctor no longer has such a hard time in getting from one place to another. The automobile and better roads have revolutionized in a great measure the hardships that we formerly experienced.

After four years in the practice of medicine in Frances-town, New Hampshire, I moved to Milford for several reasons. One was that the work was so hard that I could not stand it. I was quite rugged, too. The other was that my father, the owner of a great farm on which I was born and brought up, was very ill, and I thought that it was my duty to be where I could help him. I am getting along in years and most of my friends and associates and co-workers in medicine and surgery have passed on.

An eminent lawyer in a neighboring town said to me one day, "Doctor, ever since I was fifty years old, I feel that I have been occupying most of my time burying my friends. And that really occurs to me very often. Although the life span has increased and people live to be older, there are just as many dying as ever did but this comes in the old age variety of disease, which makes it a rather hopeless task to attempt to effect a lasting cure. Medicine is hard work. We meet much prejudice and we meet people with set ways, who are unwilling, some times to abandon their notions of remedies and to follow our desired prescriptions. But we keep busy, and that is the answer to it all."

Being somewhat aged myself, I am now pretty well able to experience some of the symptoms that our patients display, and to know whether or not they are telling the truth. It is a human frailty to exaggerate sometimes and to misrepresent intentionally or otherwise, the symptoms as well as to minimize them, and to refuse to follow set directions, and that constitutes one of the hardest obstacles in the practice of medicine. If a person will not cooperate it makes an incomplete piece of work, and our work is hard enough as it is, without these obstacles.

An ex-president of the Society, not many months ago, made this remark to me, "Doctor, do you realize the difference in the preparation of the graduate from the medical school of today and what it was when you were graduated?" I said to him, "My dear man, I have recognized that every moment of my life. We did not have

the facilities presented to us to round out our courses and make things easy that are presented today. And, today, not only are they presented free but they are required. That is true in obstetrics, and it is true in surgical technique and various other things, and it is a great advantage.

And my ex-president friend continued, "When the doctors nowadays start out, they are several laps ahead of you fellows when you started. Do you realize that?" And I said, "I certainly do. It keeps me busy reading and studying and trying to keep abreast of the times. But it is work, and it is work that I love and that I shall follow so long as I have the strength to do so. There is no better remedy for the blues or for discouragement than hard work. Since this is my chosen occupation in life, it will follow with me to the end."

Major Weir, in the absence of General Bowen spoke as follows

General Bowen called me up a short time ago in announcing that he could not come here, but he did want me to express to the members of the Society his sincere thanks for the co-operation shown to him during the past year. He said that without that co-operation the Selective Service System could not have functioned at all smoothly, and from my own point of view, I want to thank all the physicians of the Society who have been in selective service work for their co-operation with me. I think we can say that the record of the Society is unmatched, in that I do not believe there has been one resignation from the system except for illness, or moving out of the State.

Secretary Metcalf then read the following resolution concerning the resignation of Dr. Henry O. Smith as a trustee

WHEREAS, the House of Delegates learns with regret of Dr. Henry O. Smith's desire to retire from the Board of Trustees,

THEREFORE BE IT RESOLVED, That the House express to Dr. Smith its deep appreciation of his outstanding service to the New Hampshire Medical Society in the promotion of its best interest through his wise counsel and active participation in all its affairs during the many years of his membership.

Dr. Metcalf continued as follows

The House of Delegates directed the Committee on Child Health to co-operate with the appropriate state and federal agencies to immunize, against diphtheria and smallpox, all children over nine months of age.

It awarded \$50 to the Cancer Committee to carry on its work for the coming year.

It decided to be a cosponsor in the New England Health Institute, which meets in New Hampshire in 1943. Details of this co-operation were left to the Committee on Public Health.

It accepted a bill concerning medical service corporations drawn up by Mr. Sulloway, and directed me to submit it to the Committee on Public Relations, who will submit it to the Legislature next year for their consideration.

The House of Delegates decided to co-operate with the National Physicians Committee, and it requests the members of each county society to contribute \$1.00 apiece. The Committee on Public Relations is to co-operate with the

National Physicians' Committee, the county secretary to turn the money over to the Treasurer, to be forwarded. That is for the expenses of the National Physicians' Committee.

It directed the Committee on Public Health to co-operate with the State Board of Health, to determine the minimum requirements for first-aid rooms in industry.

It directed me to write to our senators and representatives about a bill in Washington that would permit osteopaths to serve in the United States Army hospitals.

It directed me to notify Congress that they were opposed to a change in Section I of the Revenue Laws, which would permit the taxation of charitable and educational institutions.

It decided to cover the cost of the Procurement and Assignment Service from the general funds of the Society, so that we may run that service and not have it run by a federal agency.

It decided that residence in New Hampshire is not necessary for membership in the Society. Two or three men who formerly lived here and who now live outside the State wish to continue as members.

The House of Delegates decided to come to Manchester again in 1943. The meeting will presumably be held on May 11 and 12. You will be glad to know that I have already started to work on the 1943 program.

Your new vice-president is Dr. James W. Jameson, of Concord. Your new president is Dr. Timothy F. Rock, of Nashua. Dr. Sanders, of Claremont, was elected vice-president last year, and would naturally have moved up to the presidency. He said that he was unable to carry on the work of the presidency, so that Dr. Rock was elected in his place.

Dr. H. O. Smith then presented the report of the Trustees.

FINANCIAL REPORT OF THE TRUSTEES OF THE NEW HAMPSHIRE MEDICAL SOCIETY FOR THE YEAR ENDING JANUARY 1, 1942

Receipts

Interests on various deposits, other than Benevolence Fund	\$317.12
--	----------

Expenditures

Expenses of meeting (Sesquicentennial) 1941	1,000.00
Pray and Burnham prizes	100.00
Total expenditures	1,100.00
Decrease in funds, other than Benevolence Fund	782.78

GENERAL FUND	
Deposits. New Hampshire Savings Bank	\$4,859.13
Portsmouth Trust and Guarantee Company	2,005.46
Nashua Trust Company	205.18
United States Defense Bonds, Series "G"	3,000.00
Total funds available on January 1, 1942	\$10,069.77

BARILETT FUND	
Deposit: Portsmouth Savings Bank (\$352.11 of this is a permanent fund, the income to be "expended only for the benefit of medical science, as may be directed by vote of this society")	\$2,718.19
United States Defense Bonds, Series "G"	2,000.00
Total funds	\$4,718.19

PRAY FUND	
Deposit: Strafford Savings Bank (\$1000 of this is a permanent fund, the income to be expended only for prize essays)	\$217.41
United States Defense Bonds, Series "G"	1,000.00
Total	\$1,217.41

BURNHAM FUND	
Deposit: New Hampshire Savings Bank (\$1140 of this is a permanent fund, the income to be expended only for prize essays)	\$1,237.32
United States Defense Bonds, Series "G"	1,000.00
Total	\$2,237.32

BENEVOLENCE FUND	
Deposit: New Hampshire Savings Bank (\$394.50 of this is accrued income available for the purposes of the fund)	\$1,385.69
United States Defense Bonds, Series "G"	3,000.00
Total	\$4,385.69

A prize of \$100.00 was awarded for a paper entitled "Dermatotherapy as Applied to Diseases of the Eyelids" by "Eidal," pseudonym for Dr. Arthur Linksz, and also a prize of \$50.00 for a paper entitled "Prostatic Hypertrophy" by "John H. Doe," pseudonym for Dr. Rolf Lium. The accounts of the Treasurer have been examined and found correctly cast and properly vouched.

HENRY O. SMITH
SAMUEL T. LADD
FREDERIC P. LORD, Secretary

The scientific session was concluded by an address, entitled "Recent Treatment of Gonorrheal Infections in the Female," which was presented by Dr. Fred L. Adair, of Chicago.

The banquet was held at the Hotel Carpenter, with Dr. Ralph W. Tuttle as toastmaster. President-Elect Timothy F. Rock, of Nashua, and Governor Robert O. Blood spoke very briefly. Dr. Ernest E. Lyons then presented an address, entitled "The Last Illness of Sir Joshua Reynolds," and showed many lantern slides of paintings. This was followed by a talk by President Dolloff.

CASE RECORDS OF THE
MASSACHUSETTS GENERAL HOSPITALANTE-MORTEM AND POST MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 28441

PRESENTATION OF CASE

First admission. A fifty-two year-old truck driver came to the hospital because of swelling of the abdomen.

Five years prior to admission the patient noticed that his abdomen was becoming swollen. Three years later he noticed a feeling of abdominal fullness that developed approximately twenty minutes after eating. At times, especially when constipated, this was accompanied by pain on both sides of the abdomen at about the level of the umbilicus. These symptoms were relieved by soda. At the same time he noticed the appearance of a yellowish discoloration of the skin, unaccompanied by nausea, vomiting, pain or clay colored stools. He also developed exertional dyspnea and ankle edema. One year before entry, urinary urgency, frequency, hesitancy and dribbling and nocturia developed. These symptoms became progressively worse to the day of admission. There was no loss in weight or any blood in his urine or stools. For many years he had occasionally drunk 3 or 4 ounces of whisky each day, but usually it was less; however, his diet was said to have been quite adequate.

His wife and two children were living and well. His wife had had no miscarriages.

The patient was born in Italy and came to America at the age of three. His vision had recently become poor, but there was no double vision, blurring or spots before the eyes. At the age of eighteen or nineteen, he had had gonorrhea without known sequelae. He denied a penile sore.

Physical examination revealed a heavy set man who appeared slightly dyspneic. The skin and sclerae were obviously yellow. The abdomen was "massive," tense and bulging. There was a marked wasting of the soft parts of the face, arms and chest. No odor of acetamide was detected on the breath. There was a marked degree of clubbing of the fingers and toes. The chest was barrel shaped. Examination of the lungs was negative except for bilateral posterior basal rales. The heart was not enlarged. A loud systolic murmur was audible over the entire precordium but best heard in the fourth interspace to the left

of the sternum. A fluid wave was easily elicited, and there was shifting dullness. Rectal examination revealed internal and external hemorrhoids. The prostate was nodular and not tender. There was edema of both lower extremities.

The blood pressure was 144 systolic, 60 diastolic. The temperature was 98°F, the pulse 81, and the respirations 20.

Examination of the blood revealed a hematocrit of 17.0 per cent, a red cell count of 2,250,000, with a hemoglobin of 22 per cent, and a white cell count of 2300 with 71 per cent polymorphonuclears. In the blood smear there was extreme variation in the size and shape of the red cells. Many macrocytes were present, but the average size of the red cells was below normal; there was no polychromatophilia; the granulocytes appeared old. The urine had a specific gravity of 1.015, and the sediment contained 2 white cells, a rare red cell and occasional epithelial cells and coarse granular casts per high-power field. The blood Hinton and Wassermann tests were positive. The van den Bergh test was first reported normal; when repeated four days later it was said to have been slightly above normal with a biphasic reaction. The blood protein was 5.4 gm per 100 cc. The prothrombin time was 22 seconds (normal, 20 seconds).

Roentgenograms of the chest showed slight generalized cardiac enlargement. The aorta was not remarkable, and the lung fields were clear. An abdominal paracentesis yielded 5000 cc. of clear fluid with a specific gravity of 1.012 and a cell count of 900. The fluid did not clot on standing. The spinal fluid was essentially normal; the total protein content was 30 mg. per 100 cc, the colloidal gold curve 0012211000, and the Wassermann test negative.

After paracentesis an irregular mass was felt below the costal margin, which was believed to be the liver. On the seventh day after admission, under local anesthesia, a peritoneoscopy was performed; 6500 cc of straw colored fluid was aspirated. The liver could not be seen anywhere because thick masses of omentum were adherent to it over both lobes. On the left the omentum was also adherent to the anterior abdominal wall and was very vascular suggesting a spontaneous omentopexy. From the general point of attachment of the omentum from inspection and from percussion after removal of the fluid, it did not appear that the liver was enlarged. The lower abdomen and pelvis appeared normal. The patient received supportive and antisyphilitic therapy, including potassium iodide and bismuth subcitrate, and was discharged moderately improved on the twelfth day.

Second admission (seven months later). Following discharge, the patient did poorly. Ascites reaccumulated rapidly, and during the month prior to admission required a tap every four to six days, when 4000 to 5000 cc. of fluid was recovered. Intermittent jaundice had been observed in the Out Patient Department. The potassium iodide and bismuth subsalicylate had been continued. The patient's appetite had been fair, although he severely limited his fluid intake. On the day of admission he developed a dull aching pain beneath the right costal margin.

Physical examination revealed a thin, emaciated dyspneic man who was obviously acutely and chronically ill. The skin was dry, yellow and sallow. There were multiple port-wine telangiectases over the hands and forearms. Expansion of the chest was limited. There were diminished to absent breath sounds over this area with decreased tactile and vocal fremitus. There was flatness to the level of the fifth interspace posteriorly and laterally. Multiple coarse rhonchi were audible in both chests. The heart was not enlarged. There was a great deal of abdominal fluid. After withdrawal of 6000 cc. of fluid the liver edge was felt four fingerbreadths below the costal margin; the edge was rough and not tender. The abdominal-wall veins were prominent. A mass could be felt in the left upper quadrant. An umbilical venous hum was audible. There was a moderate pitting edema of the legs and abdominal wall.

The blood pressure was 120 systolic, 60 diastolic. The temperature was 98°F., the pulse 82, and the respirations 20.

Examination of the blood revealed a red-cell count of 1,920,000 with a hemoglobin of 3.2 gm. and a white-cell count of 10,600 with 78 per cent polymorphonuclears. The smear resembled that of the first admission. The urine and stool examinations were negative. The blood protein was 5.6 gm. per 100 cc. An x-ray film of the chest revealed extensive increased density involving the lower two thirds of the left lung field, more marked laterally. The heart was about normal in position. Abdominal paracentesis was repeated several times, but the fluid reaccumulated rapidly. A thoracentesis yielded 1100 cc. of dark-amber, slightly cloudy fluid. This did not represent all the chest fluid, since dullness was still present to the fifth interspace.

Terminally, the patient was very uncomfortable because of dyspnea. Hoarseness developed, and the patient talked with a whisper. Examination of the larynx revealed a moderate edema of the arytenoid cartilages, which somewhat limited the excursion of the true cords; the airway was perfectly adequate. The patient became drowsy

and stuporous, and died on the sixteenth day after admission.

DIFFERENTIAL DIAGNOSIS

DR. WILLIAM B. BREED: This morning I read this case over once, and am therefore only one reading ahead of you. I shall set up the diagnosis that I have in mind, and perhaps between us we shall be able to support it—or discredit it. I will say, to begin with, that I think this man had portal cirrhosis of the liver with superimposed hematoma. Now let us read the material presented. Please give as much thought as you can to it with that diagnosis in view, and if you do not like the way things are going, please interrupt at any time.

* * *

Now that we have read the story again, I wonder if anyone is interested in the original diagnosis that I set up. (No answer.) Is anyone disinterested? (Silence.) This is an open forum; everyone's opinion has equal standing.

First of all, let us see if we can account for everything on the basis of syphilis, which has to be considered in view of the positive Hinton test. He obviously had liver disease. I do not know very much about diffuse syphilis of the liver. It is quite uncommon. Gummatous involvement of the liver is the commonest form of liver disease in syphilis, but such a manifestation should respond to iodides and bismuth, which apparently this did not. I see no other evidence anywhere of syphilis, such as aortitis, aneurysm or nervous-system involvement, and so I am willing to ignore the positive Hinton test as being the only indication of syphilitic infection and, therefore, not important as a cause of this man's illness and death.

Did he have metastatic cancer? That is the other most obvious alternative. As to cancer of the prostate, I noticed that the prostate was nodular but not tender. It does not say how hard it was. How long ago was this man in the hospital?

DR. TRACY B. MALLORY: About a year and a half ago.

DR. BREED: Even a year ago it is probable that if they thought that the patient had cancer of the prostate with metastases they would have castrated him. Cancer of the prostate, moreover, does not as a rule metastasize to the liver. It may do so but the metastases are usually in the bones, in the lungs and in the brain. Is that not correct, Dr. Mallory?

DR. MALLORY: The bones above all.

DR. BREED: Thank you. We have no evidence here to make a diagnosis of cancer of the prostate. He had urgency and frequency at one time, but we do not know whether it persisted. There

was no obstruction to the urinary output. I am not willing to make a diagnosis of cancer on the lone statement that he had a nodular prostate.

We have enough here to make a diagnosis of portal cirrhosis. He had ascites and a history of alcohol, even though his diet was said to have been adequate. It is too bad that we have no

extremely low figure. Toward the end the patient accumulated fluid in his left pleural cavity. That is perfectly all right in the presence of cancer in the liver even though the fluid was not on the right side—the more usual site.

There are still some findings that I cannot adequately explain. The question is, Are most of

FIGURE 1

x-ray films of the esophagus or some liver-function test. I am surprised that they were not done, because I suspect that he was discharged the first time with diagnoses of portal cirrhosis and syphilis. It seems to me that they should have tried a little harder to confirm the former.

What about the clubbing of the fingers? That is a hard one. I am going to say that it was congenital clubbing of the fingers. He had nothing on physical examination or by x-ray study to indicate a systemic cause of clubbing of the fingers, except possibly a congenital heart lesion. We know he had some enlargement and a loud systolic murmur on the left side of the sternum. He may have had a congenital lesion, but I doubt it. There were no other manifestations, such as cyanosis and typical murmurs. The reason I suspect he had cancer of the liver is the extreme degree of anemia and the rapid downhill course once he became sick. Apparently for five years he had had some fullness in the abdomen, which I explain on the basis of early portal cirrhosis, and during the last year of his disease he went downhill rapidly and developed a severe degree of anemia. The low white-cell count in the beginning is consistent with liver disease. The serum protein, if accurate, was depressed, but not to an

the things that appear here consistent with one diagnosis? Assume, for the moment, that we have ruled out syphilis and metastatic cancer from either the prostate or gastrointestinal tract, which by the way was not examined. That leaves us with malignant disease in the liver superimposed on what appears to be portal cirrhosis, and congenital clubbing of the fingers.

The peritoneoscopy does not help us at all, except to show that there had been adhesions and that the omentum had been pushed up against the liver to create a spontaneous omentopexy. I am going to assume that the mass in the left upper quadrant felt after paracentesis was an enlarged spleen. That is the commonest mass felt in the left upper quadrant. The hoarseness without obvious signs of paralysis does not interest me very much. There was no evidence of pressure on the trachea. There was only moderate edema of the arytenoid cartilages, and no paralysis of the cords. Aside from syphilis and metastatic cancer, what else may he have had? Has anyone here, having read this over with me, other suggestions as to the cause of this man's illness and death? (No answer.) Then I take it we all agree that I have mentioned at least three of the most likely diagnoses.

DR. RICHARD H. SWEET: Why is it necessary to assume that the patient had a primary cancer of the liver or hepatoma? Why does not cirrhosis account for the whole picture?

DR. BREED: I say that because he went downhill so rapidly, with such a severe degree of anemia and fluid in the chest.

DR. SWEET: That is inconsistent with cirrhosis alone?

DR. BREED: I believe so.

DR. ALLEN G. BRAILEY: The history covers a period of five years!

DR. BREED: We do not know how much anemia the patient had until seven months prior to death, when the anemia was discovered. How do you know he had anemia for a longer period of time? It says that for five years he had had swelling, that for two years there had been fullness and that for only a year previous to admission he had had these new symptoms. For a year and a half he was incapacitated, and in seven months he was dead.

DR. REED HARWOOD: I am not impressed with the rapidity of the patient's down-hill course. He had severe anemia—a red-cell count of 2,000,000—seven months before he died. Seven months is a long period to live with an anemia of that severity due to cancer, is it not?

DR. MALLORY: There is one thing that is not clearly brought out in the summary. He had an enlarged spleen, but several examiners thought that they could feel another epigastric mass, which seemed to be attached in some way to the liver.

DR. BREED: We know by peritoneoscopy that he had a mass of omentum stuck up against the liver. Do you think one could have felt this mass of omentum through the abdominal wall, Dr. Sweet?

DR. SWEET: I doubt if one could unless there was something in it.

DR. BREED: Why, in all this time, if they felt an epigastric mass and suspected cancer or a lesion in the gastrointestinal tract, did they not investigate it? They could not have thought much of it because they sent him home with no diagnosis so far as the gastrointestinal tract was concerned. If they did that, how can I be expected to add to the diagnosis now? I also wonder a little bit why they did not think enough of the diagnosis of portal cirrhosis to go farther with it. Did they?

DR. BENJAMIN CASTLEMAN: Do you think that they may have made a diagnosis of syphilis on the first admission and sent him home on anti-syphilitic treatment to see what would happen?

DR. BREED: That seems obvious. They sent the patient home under treatment with a diagnosis of syphilis. He did not do well and re-

turned. Nothing further was done to establish a diagnosis. I still think that they should not have been quite so certain that this was syphilis, even though he had a positive Hinton test. I do not believe the diagnosis was accurate enough.

DR. MALLORY: Assuming that the history is correct and that he took never more than 3 or 4 ounces of whisky a day and usually less, do you still maintain that your diagnosis of portal cirrhosis is correct?

DR. BREED: I do not quite get the import of that question.

DR. MALLORY: I am asking a personal question, Dr. Breed. If the history of alcoholic intake is correct, do you want the patient to be proved to have portal cirrhosis?

DR. BREED: From a personal point of view? No. Seriously, however, I question the adequacy of his diet.

Have you any other suggestions that might set me right? I can see that the wind is blowing the wrong way. Is not someone here brave enough to come forward and help out Dr. Mallory? He has something on his mind. It is not because you do not want to speak up but because you do not know, is that right? (No answer.) Then I shall have to leave it that way.

CLINICAL DIAGNOSES

Portal cirrhosis.
Banti's syndrome.
Syphilitic cirrhosis?
Asymptomatic syphilis.

DR. BREED'S DIAGNOSES

Portal cirrhosis.
Hepatoma.
Latent syphilis (serologic).

ANATOMICAL DIAGNOSES

Syphilitic cirrhosis of liver (hepar lobatum).
Icterus.
Splenomegaly.
Ascites.
Hydrothorax, left.
Pulmonary atelectasis, left lower lobe.
Osteoarthropathy: fingers and toes.
Pulmonary tuberculosis, healed: apical, bilateral.

PATHOLOGICAL DISCUSSION

DR. MALLORY: Some years ago, I looked up all the cases of syphilis of the liver that had come to autopsy, and out of 20 cases, 18 were accidental findings at autopsy without referable symptoms in the clinical history. Two had symptoms; but in one of these there was amyloid disease, which may well have been responsible for the ascites, so that

left only 1 out of 20 patients who did have symptoms.

Syphilis of the liver is what this man had. The liver was considerably smaller than normal. It presented marked deep fissures dividing it into eight or ten lobes instead of the normal five (Fig 1). You will note there is an almost pedunculated mass that dangles from the hypertrophied left lobe; this probably was at some time felt as the epigastric tumor. The shrunken right lobe is completely wrapped in omentum. When nodules are actually felt on a liver, it always means either tumor or syphilis of the liver. In a patient with symptoms of cirrhosis of five years' duration the recognition of palpable nodules on the lower margin of the liver would have led me to make the same diagnosis as Dr. Breed did; it seems the most reasonable one. I should hardly have expected a liver of this sort to have produced the characteristic symptoms of cirrhosis lasting over a period of five years.

I think the reason this patient made no improvement on syphilitic therapy is that the active stage of gumma formation was past history, when they started treating him he already had a scarred liver and one could hope to accomplish nothing with treatment.

There is no explanation of the marked hydrothorax on the left except the presence of ascitic fluid. Whenever there is ascitic fluid, it never surprises me to see a pleural effusion develop, although it is more apt to appear on the right than on the left; but it can develop on either side, as in the cases of ovarian fibroma that Dr. Joe V. Meigs has called to our attention.

We found no other evidence of syphilis. He had a normal cardiovascular system. He did not have anything wrong with the urinary tract.

DR. BREED: Was the clubbing of the fingers and toes congenital?

DR. MALLORY: I do not believe so. It was probably due to cirrhosis. A significant number of cases of cirrhosis of the liver have clubbing of the fingers.

A PHYSICIAN: What about the prostate?

DR. MALLORY: It was normal.

CASE 28442

PRESENTATION OF CASE

A forty seven year old man was admitted because of severe abdominal pain.

The patient was known to have had a high blood pressure for many years but had been quite well until one month before entry. At this time he had an attack of moderately severe substernal

pain, which lasted two days and then cleared completely. During the succeeding month he was well and active. Several hours prior to admission he developed an excruciating pain centered in the lower abdomen. At times he believed the pain radiated into the legs. There was no radiation of this discomfort to the chest. He vomited once. The patient collapsed soon after the onset of the pain and was immediately brought to the hospital. After reaching the hospital he noticed numbness of the right arm.

Physical examination revealed a semicomatose, thickset man lying quietly in bed complaining of severe lower abdominal pain. There was no cyanosis or dyspnea, and the neck veins were not distended. The examination of the lungs was negative. The apex impulse of the heart was felt in the fifth interspace, 11 cm. to the left of the midsternal line, which was 3 cm. beyond the midclavicular line. A rather harsh, moderately strong, systolic murmur was audible at the base of the heart in the aortic area and was transmitted to the neck, to the left of the sternum, and to the apex. A loud blowing diastolic murmur was heard in the aortic area, but was transmitted to the cardiac apex. The aortic and pulmonic second sounds were equal in intensity. The abdomen was soft and slightly protuberant, with rather generalized tenderness in the upper portion. A systolic murmur was prominent in the epigastrium; the peristaltic sounds were normal. The right arm was pulseless and slightly cooler than the left.

The blood pressure was 205 systolic, 95 diastolic, in the left arm; it could not be obtained in the right arm. The blood pressure was 220 systolic, 95 diastolic, in both legs. The pulse in the left arm was regular and of good quality, with a rate of 60. The temperature was 97.8°F.

An electrocardiogram showed a normal sinus rhythm with a rate of 50. T₁ was low and diphasic. The T waves were very low in Leads 2 and 4, and T₃ was high. P₁ was diphasic. There was a considerable amount of left axis deviation.

Several hours after admission the patient said he felt better and indicated that the right arm was less numb and his feet less cold. The right hand and arm remained cool, but there was a weak but definite radial pulse. Four and a half hours later, less than twelve hours after reaching the hospital, the patient expired quietly within two or three minutes.

DIFFERENTIAL DIAGNOSIS

DR. REED HARWOOD: After reading the first two sentences I think we should consider the

possibility that this man had had a myocardial infarction. We might think then, if it were not for the numbness in his arm, that this episode of excruciating abdominal pain was the result of the separation of an embolus from a mural thrombus, which lodged in the bifurcation of the aorta. It is unusual for a man who has had severe pain to become semicomatose so suddenly. The fact that he had no cyanosis, dyspnea or signs in his lungs shows that he was not in congestive failure. The position of his heart suggests an enlarged left ventricle or possibly that the heart had been pushed to the left.

He might have had a systolic murmur for many years. He had had hypertension for a long time, and he might have had previous disease of the aortic valve. Probably he did not have the loud blowing diastolic murmur before the onset of his present illness. I say this because he was known to have had hypertension for a long time, and I should think that the doctor would have detected a loud blowing diastolic murmur. I think we can reason therefore that he did not have the diastolic murmur for more than a few hours. He probably did not have the systolic one for much longer either; otherwise, I think it would have been mentioned in the record.

Let us consider then the possible causes of a diastolic murmur in the aortic area. The first that comes to mind is syphilitic aortitis. He would have had a murmur of aortic regurgitation for a long time if he had had syphilitic aortitis. The same is true if he had had rheumatic heart disease with aortic regurgitation. I am going to exclude these two diagnoses on the basis that I believe that this murmur was of very short duration. Another possibility to be mentioned only to exclude it is rupture of the aortic cusp. I know very little about this condition, but I do not believe it would produce the numbness in the right arm and so forth. Although he had signs of aortic regurgitation, there is one very interesting finding—namely, the aortic and pulmonary second sounds were equal in intensity. I am going back to that and explain the probable mechanism when I have made my diagnosis.

The fact that the blood pressure in the legs was essentially the same as in the left arm rules out fairly well the possibility of a rider embolus.

I think we can interpret the electrocardiogram as follows: the interpreter was trying to find something abnormal, but he had to admit in the end that the patient did not have anything suggesting coronary thrombosis or myocardial infarction. It did suggest, however, that the patient had left ventricular hypertrophy, as shown by the axis deviation. This is consistent with the story of long-continued hypertension. The electrocardio-

gram, to my way of thinking, rules out quite well the possibility of myocardial infarction two months ago, and we can dismiss that diagnosis here and now.

In summary, the patient had severe pain in the abdomen, numbness and lack of pulse in the right arm and died suddenly. I can think of only one diagnosis that will fit the findings in this case and that is dissecting aneurysm. We might argue that the age, forty-seven, was rather young for that condition. However, I have seen cases reported considerably younger. So I do not believe we need to rule out the possibility of dissecting aneurysm on that single finding. Then there is the question of whether he had syphilis as a basis for his aneurysm. Dissecting aneurysm can occur in patients with syphilis in the aorta and cases have been reported. The late Dr. Soma Weiss, however, believed that if dissecting aneurysm did occur in a case of syphilitic aortitis it was coincidental rather than a result of the syphilitic process. In fact there is some suggestion that the inflammatory process of syphilis may protect the patient against this accident. I am going to say that he probably did not have it.

There is another interesting point that I want to discuss—that is, the matter of his being semicomatose. Patients with severe, sudden onset of pain in the abdomen and chest do not become comatose suddenly unless they have a sudden lowering of the blood pressure that is sufficient to produce cerebral anemia. We know that this patient did not have sudden lowering of the blood pressure, but may he not have had an anemia, at least of one cerebral hemisphere? We notice he was pulseless in the right arm. If he had a dissecting aneurysm, this means that the dissection must have involved the right innominate artery. In keeping with this is the fact that at the time when a weak but definite pulse could be found, he was not semicomatose and was able to say he felt better. Then, while he seemed to be improving, he suddenly died.

Dissecting aneurysms very frequently rupture somewhere along their course, and I think the most frequent location of rupture is into the mediastinum or into the pericardium. Either of these is rapidly fatal, and I do not see how we can distinguish between them. It is possible also that the aneurysm could have ruptured into the abdominal cavity, but in that case I do not believe he would have died so suddenly. So I am going to say that he had dissecting aneurysm of the aorta originating probably in the arch or in the descending portion of the arch, which dissected its way to the aortic ring and down through the abdomen and stopped somewhere in the region

of the bifurcation. He also probably had left ventricular hypertrophy.

I said that I was going to explain why he had the loud blowing diastolic murmur and still had an audible aortic second sound. Perhaps I should have said that I was going to try to explain it. I believe that the aneurysm distorted the aortic ring in such a way that a diastolic murmur was produced. Although the cusps clicked shut momentarily, it is probable that some blood did leak back into the heart.

CLINICAL DIAGNOSIS

Dissecting aneurysm of aorta.

DR. HARWOOD'S DIAGNOSIS

Dissecting aneurysm of aorta.

ANATOMICAL DIAGNOSES

Dissecting aneurysm of aorta, with perforation into the pericardium.

Hemopericardium.

Media necrosis cystica aortica.

Nephrosclerosis.

PATHOLOGICAL DISCUSSION

DR. MALLORY: The same diagnosis as Dr. Harwood's was reached on the ward and was substantiated at autopsy. There was an extensive dissecting aneurysm with a tear in the intima of the aorta about 3 cm. above the aortic valve. It dissected back as far as the annulus, partially surrounded the mouths of the coronary arteries but did not occlude them. It also dissected forward over the arch for a short distance into the innominate and left carotid arteries and 3 cm. down the left subclavian artery. In the subclavian, it had failed to rupture back through the intima so the subclavian was completely blocked by a projecting knuckle of intima. Dissection continued down the thoracic abdominal aorta into both iliac vessels, but in each of these rerupture of the intimal layer had occurred, so that the circulation was quickly re-established in both legs, if it was ever completely interrupted. There was a dissection for 1 cm. along the superior mesenteric artery,

but again there was either no interference with the blood supply to the bowel or only a transitory one, because there was no discoloration of the intestines.

We found nothing to suggest that the aortic valve was not functioning perfectly well, and I have no clear explanation of the diastolic murmur. One is heard, however, every once in a while in these cases of dissecting aneurysm. It is at least possible that the jagged, rough tear in the intima creates a V-like flap between one column of blood in the old lumen of the aorta and the other column in the newly formed vessel outside. One can imagine it flapping back and forth to make an odd variety of murmurs, perhaps in both systole and diastole. The immediate mechanism of death, as Dr. Harwood prophesized, was rupture into the pericardium, with cardiac tamponade. The kidneys showed moderately severe nephrosclerosis.

DR. ALLEN G. BRAILEY: What do you think of the coma? It was not shock?

DR. MALLORY: It is hard to see how it could have been shock when the systolic blood pressure was 220. I should think that the carotid artery may have been temporarily obstructed by external pressure. There was no extensive dissection along the carotid.

The aorta in this case showed a very good example of so-called "media necrosis cystica," which is often to be found in cases of dissecting aneurysm. It is a condition that occurs only in elastic arteries, and the dissection is ordinarily limited to arteries that have this elastic structure. For that reason, dissection extends only a very short distance along most of the branches of the aorta, such as the coronary and renal vessels, which are muscular arteries, but may extend several centimeters along the subclavian and iliac vessels, which have a structure similar to that of the aorta.

DR. BRAILEY: Is this always associated with high blood pressure?

DR. MALLORY: I cannot answer that accurately.

DR. HOLMES: There was no evidence of syphilis?

DR. MALLORY: No; in a dissecting aneurysm, there almost never is.

perience in medical defense. Dr. Arthur W. Allen, chairman of the Committee on Medical Defense of the Massachusetts Medical Society, states that the record

the facts presented, each member may better select that insurance company which meets his individual needs best. Reliability is paramount, experience in the field is of con-

TABLE I. Comparative Rates for Malpractice Insurance.

*Less 20 per cent, if earned

of this company in this state is good. As has been mentioned, their suit experience in Essex County is very high.

The *United States Fidelity and Guaranty Company* (assets, \$30,000,000) has not had a high suit rate in Essex County. They retain the law firm of Powers and Hall, in Boston, who have had a wide experience in defending malpractice suits. In their policy they have a dissolve attachment bond feature. Dr. Allen says that their record in this work is good. This company advises minimum limits of \$10,000–\$30,000, and believes so strongly that these limits are necessary that it does not write for less. On the other hand, the Medical Protective Company believes that \$5000–\$15,000 limits are sufficient, and will not write for more in Essex County.

The *American Motorists Company* (assets, \$10,000,000), a subsidiary of the Lumbermens Mutual Insurance Company (assets, \$41,000,000), is relatively new in the medical-defense field, although they have been in Massachusetts for ten years and now collect \$13,000 in premiums for this type of insurance. They advise \$10,000–\$30,000 limits, but will write for less.

The *Metropolitan Casualty Company* (assets, \$11,000,000) has been official for the Massachusetts Dental Society for nearly twenty-five years. A prominent feature of their policy provides payment of premium on appeal bonds without limit. This company pays \$15 a day for not more than seven days to the defendant doctor for loss of time while in court.

While this study was in progress, and after one set of rates had been offered, Ladd and Milne, in Haverhill, obtained the following concession from the American Motorists Insurance Company, which they represent: for all physicians in Essex County, whether engaged in general practice, major surgery or another specialty, but excluding those physicians using x-ray and radium for therapeutic purposes, the premium of \$20.00 for \$5000–\$15,000 limits is offered; for \$10,000–\$15,000 limits, \$24.00; and for \$10,000–\$30,000 limits, \$26.00. The company states that if a substantial amount of the business in this county is obtained over a period of one year, the rate will continue. No assessment can be made against the policyholder, and a dividend of 20 per cent, if earned, is returned to him. It is a legal reserve stock company, but is owned and operated by the Lumbermens Mutual Insurance Company. According to Ladd and Milne, the company offers this rate schedule only through their agency.

In summary, this committee chooses to recommend no one company for all the members. It is hoped that from

siderable importance, and a reasonable rate is desired. The committee will gladly assist any member by allowing him to examine any of the data and all the letters that we have collected as a result of this investigation.

NEW HAMPSHIRE MEDICAL SOCIETY

DEATHS

COTTON — CURTIS B. COTTON, M.D., of Wolfeboro, died August 6. He was in his seventy-eighth year.

Dr. Cotton, the son of Joel F. and Elivna (Gilman) Cotton, was born in Moultonboro and graduated from the University of Vermont College of Medicine in 1888. He was a member of the New Hampshire Medical Society and the American Medical Association.

He is survived by his widow, a son and a sister.

ROWE — ARTHUR J. ROWE, M.D., of Penacook, died September 9. He was in his seventy-fifth year.

Born in South Barnstead, the son of Dr. James W. and Emma (Clark) Rowe, Dr. Rowe received his degree from Dartmouth Medical School in 1899. He was a member of the New Hampshire Medical Society and the American Medical Association.

He is survived by his widow, Mrs. Ida (Avery) Rowe, three brothers and a sister.

WAR ACTIVITIES

PROCUREMENT AND ASSIGNMENT SERVICE

The following release was recently received from the Washington office of the Procurement and Assignment Service:

The Directing Board of the Procurement and Assignment Service is pleased to announce that 95 per cent of the 1942 procurement objective of medical officers for the armed forces has already been met. Toward this total a number of states have supplied more than their share of physicians. Only a few states are lagging behind in their quotas, and it is from these states that the additional physicians needed during the current year should come.

The recruitment of such a large number of physicians in a few months is a remarkable achievement and another demonstration of the traditional patriotism and unselfishness of the medical profession. In this achieve-

of the bifurcation. He also probably had left ventricular hypertrophy.

I said that I was going to explain why he had the loud blowing diastolic murmur and still had an audible aortic second sound. Perhaps I should have said that I was going to try to explain it. I believe that the aneurysm distorted the aortic ring in such a way that a diastolic murmur was produced. Although the cusps clicked shut momentarily, it is probable that some blood did leak back into the heart.

NAVAL MEDICAL OFFICER PROCUREMENT

Attention is called to a letter from the Office of Naval Officer Procurement, published elsewhere in this issue of the *Journal*, which emphasizes the need for obtaining medical officers from Massachusetts. Apparently, physicians who have previously been rejected because of minor physical defects may now receive favorable consideration.

MASSACHUSETTS LABORATORY TECHNOLOGISTS RESERVE CORPS

A LETTER in this issue of the *Journal* calls attention to an extremely necessary addition to the activities of the Massachusetts Committee on Pub-

lic Safety. Because of an acute shortage of adequately trained laboratory technologists, many hospitals in the Commonwealth lack the specialized services that would be required in the event of wholesale bombing or other civil disasters. To correct this situation, the Committee on Public Safety is organizing the Massachusetts Laboratory Technologists Reserve Corps. By this means, each of the one hundred and twenty-four emergency (casualty receiving) hospitals in Massachusetts will be assigned technicians up to its needs, sometimes as many as three or four, for specialized work in an emergency.

The corps, which will consist of women trained as hospital technologists, will be organized in a manner similar to that of a military group. The members are expected to number approximately three hundred and fifty. The personnel will include both experienced technologists not at present engaged in such work and those who are already employed. Under the direction of nine regional directors, the corps will function in all parts of the Commonwealth.

The Massachusetts Committee on Public Safety is to be congratulated for its zeal in preparing the Commonwealth against possible disaster. The formation of this corps is a vital contribution to civilian defense.

THE SENESCENT SKIN

Now that the older age groups constitute a large proportion of the population, more interest has been aroused in geriatrics, but as yet, few phases of this branch of medicine have been explored to any extent. Even the most accessible organ—the skin—has been given little study.

In this issue of the *Journal*, attention is called to the many varied conditions that contribute to generalized itching in old persons. Not only local causes but also general factors, both external and internal, act to produce this symptom, which can have a very serious effect on the patient: general pruritus may be an early manifestation of a serious disease, when, by interfering greatly with sleep

and nutrition, it may thus act to lower further the resistance of a patient already combating the inroads of a disease of other organs. In general, eczema, keratoses of various types, pruritus and cancer are the commonest diseases of the skin of old persons. At the same time, it should not be forgotten that other skin diseases—those of childhood and of middle life—may be found in people of this age group and that the diagnosis may be missed by reason of failure to consider such possibilities.

Grossly, as the years pass, the skin becomes dry, thinner, less elastic and wrinkled. Pigmented areas, dilated vessels and small scaly areas may develop. Histologically, according to Hill and Montgomery,* the greatest changes occur in the collagen and elastic tissue, with some atrophy of the rete pegs. Investigation concerning the physiologic and chemical changes in the skin of this older group has received but slight attention. In addition, there is little knowledge of the effect on the skin of senile circulatory changes—the failing heart muscle, the fibrotic changes in arteries and the loss of elasticity of the veins and capillaries. Such changes cannot fail to have some relation to morbid processes in the skin. Whether the reduction in glandular activity and the subsequent dryness are results of circulatory change is not known. The effect of the aging process elsewhere or of pathologic processes in other organs is obscure. Much remains to be learned of the part played by the nervous system, by hormones and vitamins and by nutrition in aging of the skin. Truly, a large realm of investigation lies open to the explorer in this field.

MEDICAL EPONYM

SCANZONI MANEUVER

The description of this maneuver appears in "Die geburtschilflichen Operationen [Obstetric Operations]," which was issued by its author, Professor Friedrich Wilhelm von Lichtenfels Scanzoni (1821-1891), of Würzburg, in the form of a reprint, with revisions, of a portion of the third volume of his *Lehrbuch der Geburtshilfe* [Text-

book of Obstetrics] (1852). A portion of the translation follows:

Our procedure under these circumstances is as follows: If the head lies with the brow anterior and turned to the left, so that the longitudinal suture runs in the right diagonal diameter, the left blade is applied in front of the left sacroiliac synchondrosis, the right behind the right oval window [*zirunder Loche*]. . . . The head is then rotated, by turning the instrument from right to left through one eighth of a circle, so that the longitudinal suture lies parallel with the transverse diameter of the pelvis.

Both blades of the forceps are now removed and re-applied so that the left blade lies behind the left oval window, the right in front of the right sacroiliac joint, whereby the occiput may be drawn under the pubic arch by again rotating the instrument.

R. W. B.

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE ON MATERNAL WELFARE

ANALYSIS OF CAUSES OF MATERNAL DEATH IN MASSACHUSETTS DURING 1941

HEART DISEASE

In the tabulation that appeared in the first installment of the maternal-mortality study for 1941, the deaths of 42 women were attributed to medical causes. These can be broken down into the following groups:

Heart disease	22
Pneumonia	12
Hypertensive nephritis	2
Meningitis	2
Gastric ulcer	2
Tuberculosis	1
Colitis	1
Total	42

Of the 22 deaths that occurred as a result of heart disease, in 8 the patient was undelivered, 8 followed normal delivery, 5 followed operative delivery and 1 was associated with miscarriage. Autopsy was performed in only 1 case.

The undelivered cases emphasize the seriousness of heart disease during pregnancy and prove beyond question that heart disease during pregnancy alone may cause death. From this standpoint, the deaths are, of course, preventable, and the medical profession is responsible for them if its advice was sought and abortion not advised. If these patients had been told to avoid pregnancy and if they had followed this advice, the deaths would not have occurred. Religious beliefs, however, on the part of the physician or the patient may well have played a part in these fatalities.

The cases of the 8 patients who died undelivered are reviewed briefly.

The first was a patient who, at three months, developed symptoms of heart failure; she was admitted to the hospital two months later with cardiac decompensation and died undelivered, in spite of treatment. Although no autopsy was performed, this patient was known to have had rheumatic heart disease and should have been warned against becoming pregnant; and, in the event that pregnancy did take place, abortion should have been performed in the early stage.

The second case was that of a patient who had had two previous pregnancies and who was known to have a definite heart lesion; in her third pregnancy she had attacks of tachycardia and palpitation. When seven months pregnant she became acutely decompensated, entered the hospital and died a few hours later. The criticism of the first case can be reiterated here.

The third patient, who had a history of a cardiac lesion since childhood, was a primipara; she was being prepared for a cesarean section when she had acute cardiac failure and died fifteen minutes later. There is little to be said in criticism of this case.

The fourth patient was known to have had rheumatic heart disease with a double mitral lesion for years. She was seen at first by her physician when about five months pregnant, at which time she was in cardiac distress, but refused hospitalization. When seen a week later at home, she was in extremis and died shortly. This fatality can be attributed either to the patient's ignorance in not having sought medical advice earlier in pregnancy or to religious dogma. She should never have become pregnant.

The fifth case in this group was a patient who, with a history of rheumatic heart disease since childhood, was seen first at three months and again at six months, when, because of signs of decompensation, she was sent to the hospital. Her stay there lasted only six days. She should not, of course, have been allowed to go home, but she was said to have been unco-operative. When she was approximately at term, acute cardiac decompensation developed and she died undelivered. The treatment of this case was obviously unintelligent.

The sixth patient, a multipara with rheumatic heart disease, did not consult a physician until near term, at which time she had an attack of acute cardiac failure and was practically moribund at the time of his arrival. This patient was not in labor and died undelivered en route to the hospital.

In the two other cases in this group, the records are not adequate. One patient is known to have had rheumatic heart disease of long standing; she died undelivered at six months. The other had the same history of rheumatic heart disease and died near term.

The following are the records of the 8 patients who died of heart disease following normal delivery. The first was a patient who, at six months, was hospitalized and given digitalis for cardiac decompensation and who was sent home six weeks later. She re-entered the hospital at approximately eight months, being in poor condition and in mild labor. A living 4½-pound baby was delivered, but the mother went steadily downhill and died on the fifth post-partum day.

The second patient was delivered normally but developed cardiac insufficiency seven weeks post partum; in spite of treatment, she died five days after the onset of the attack.

The third patient, a multipara who gave a history of rheumatic heart disease, entered the hospital at about eight months with cardiac decompensation associated with psychosis. She delivered herself spontaneously at term; but marked decompensation immediately followed delivery, and she lived only forty-eight hours.

The fourth patient delivered herself at term after a very short labor. Since she had rheumatic heart disease, she had been warned against pregnancy; she was hospitalized at seven months because of decompensation; she improved and remained in the hospital until she went into labor at term. Following a normal delivery, she again became decompensated and died two weeks later.

The fifth case was that of a primipara with a history of rheumatic heart disease who developed definite signs of bacterial endocarditis after a short, normal labor, from which death resulted four weeks later.

The sixth patient was a multipara who had known cardiac disease associated, during her last pregnancy, with an elevated blood pressure. Labor was induced at term by rupturing the membranes, a living 9½-pound child being delivered seven hours later. Death occurred four hours after this, following the appearance of pulmonary edema.

The last two cases, whose histories are not complete, concerned patients who had long-standing rheumatic heart disease; one developed subacute bacterial endocarditis after a spontaneous delivery, and the other, having received no medical attention whatsoever during her pregnancy, succumbed from cardiac failure several hours after delivery.

Of the 5 cases of operative delivery, the first patient was delivered prematurely at seven months. At six months she developed subacute bacterial endocarditis, proved by blood culture to be due to *Streptococcus viridans*, for which she was given sulfathiazole. She started in labor at seven months and was delivered by low forceps. Death occurred a month later. There is little to be said in criticism of the handling of this case. The patient's history shows that she had chronic endocarditis, upon which the subacute bacterial endocarditis developed.

The second patient, delivered by low forceps, was one who had rheumatic heart disease of long standing and developed arterial emboli, proved by autopsy, on the ninth post-partum day. She died thirty-four days after delivery.

The third case in this group was a patient with congenital heart disease on whom a planned cesarean section was done. Although this patient had adequate prenatal care, she did not survive the operation (which was done under local anesthesia), death occurring three days later. At the beginning of this pregnancy, the question of whether or not she should be aborted was raised, but after consultation it was decided that the cardiac condition was compatible with a safe pregnancy.

The fourth patient had rheumatic heart disease and died shortly after delivery of cardiac decompensation, and the fifth patient, whose history is inadequate, died in heart block during a low forceps delivery.

The miscarriage in this series occurred spontaneously at two months in a patient who had rheumatic heart disease, death due to congestive heart failure occurred two weeks later. Nature did the best she could for this patient.

These 22 fatal cases of known heart disease complicating pregnancy represent a little more than 9 per cent of the total maternal deaths occurring during 1941. They show how serious heart disease is in pregnancy. They emphasize the importance of adequate prenatal care, which many of these patients did not have. They bring up the questions of abortion, of sterilization and of intelligent contraceptive advice. All these problems must be met if the maternal mortality from this particular complication is to be lowered in Massachusetts.

ESSEX NORTH DISTRICT MEDICAL SOCIETY

REPORT OF SPECIAL COMMITTEE ON MALPRACTICE INSURANCE

Investigation of malpractice insurance in Essex County was prompted mainly because of the statement by one

insurance company official that Essex County was a hotbed for malpractice suits. Two other reasons that led to this study were as follows: first, refusal of one company—the Medical Protective Company, Fort Wayne, Indiana—to write for amounts greater than \$5000–\$15000 limits, although this same company admitted writing higher limits outside of Essex County, and, second, the matter of premium rates—considerably higher than in former years and not the same in all companies.

We wrote to the medical societies of several nearby states to ascertain their experience with this type of insurance.

The Connecticut State Medical Society has a group-plan policy with the Aetna Life Insurance Company. Their experience with this group plan has been highly satisfactory. The limits are \$10,000–\$25,000. The rate for minimum coverage—no surgery—is \$12.50. The rate for unrestricted practice is \$16.50.

The Medical Society of the State of New York also has a group plan, with the Yorkshire Indemnity Company. Fifty to sixty per cent of the members of the society are insured under this plan. The rate is \$8.00 for \$5000–\$15000 limits, and \$36.40 for \$10,000–\$30,000 limits. These rates include all types of practice except x-ray for therapeutic purposes. The Yorkshire Indemnity Company has an agreement with the society whereby a committee from the society may inspect all the books and records of the company whenever desired. As a result of three years' experience, it was found possible to reduce the base rate \$2.00. The premium rate for x-ray therapy was dropped to \$8.00 from \$70.00—quite a difference. Complete understanding and co-operation between the society and the Yorkshire Indemnity Company make immediate rate reduction possible whenever the figures warrant it.

The Rhode Island Medical Society has a group policy with the United States Fidelity and Guaranty Company, paying \$20.00 for \$5000–\$15000 limits; practice in medicine and surgery is unlimited.

In October, 1941, to get a cross section of the amount of malpractice business each company was writing in one city, we made a survey of Haverhill, and found as follows: American Motorists Company, 7 policies in force; Medical Protective Company, 12 policies; and United States Fidelity and Guaranty Company, 22 policies. Four physicians were found to carry no malpractice insurance.

The Aetna Insurance Company retired from the malpractice field in Massachusetts in 1920 because of poor experience.

The Medical Protective Company, which has probably had the largest share of this type of business in Essex County for the last several years, found that in one recent year more than 30 per cent of the claims pending in Massachusetts were against physicians in Essex County. The last check made by them showed a reduction of this figure to 20 per cent. They give no satisfactory explanation of this preponderance of claims in Essex County except to say that the people of this county are more suit-minded.

As to reliability, record and other pertinent factors, the four companies mentioned above line up somewhat as follows in the opinion of the committee (the comparative rates are listed in Table 1).

The Medical Protective Company is relatively small as regards its capital (assets, \$2,883,700). However, they are specialists in the medical defense field, doing no other kind of business. In Boston they have an attorney—Mr. Charles Dunn, who has had much ex-

perience in medical defense. Dr. Arthur W. Allen, chairman of the Committee on Medical Defense of the Massachusetts Medical Society, states that the record

the facts presented, each member may better select that insurance company which meets his individual needs best. Reliability is paramount, experience in the field is of con-

*Less 20 per cent, if earned

of this company in this state is good. As has been mentioned, their suit experience in Essex County is very high.

The *United States Fidelity and Guaranty Company* (assets, \$30,000,000) has not had a high suit rate in Essex County. They retain the law firm of Powers and Hall, in Boston, who have had a wide experience in defending malpractice suits. In their policy they have a dissolve attachment bond feature. Dr. Allen says that their record in this work is good. This company advises minimum limits of \$10,000-\$30,000, and believes so strongly that these limits are necessary that it does not write for less. On the other hand, the Medical Protective Company believes that \$5000-\$15,000 limits are sufficient, and will not write for more in Essex County.

The *American Motorists Company* (assets, \$10,000,000), a subsidiary of the Lumbermens Mutual Insurance Company (assets, \$41,000,000), is relatively new in the medical-defense field, although they have been in Massachusetts for ten years and now collect \$13,000 in premiums for this type of insurance. They advise \$10,000-\$30,000 limits, but will write for less.

The *Metropolitan Casualty Company* (assets, \$11,000,000) has been official for the Massachusetts Dental Society for nearly twenty-five years. A prominent feature of their policy provides payment of premium on appeal bonds without limit. This company pays \$15 a day for not more than seven days to the defendant doctor for loss of time while in court.

While this study was in progress, and after one set of rates had been offered, Ladd and Milne, in Haverhill, obtained the following concession from the American Motorists Insurance Company, which they represent: for all physicians in Essex County, whether engaged in general practice, major surgery or another specialty, but excluding those physicians using x-ray and radium for therapeutic purposes, the premium of \$20.00 for \$5000-\$15,000 limits is offered; for \$10,000-\$15,000 limits, \$24.00; and for \$10,000-\$30,000 limits, \$26.00. The company states that if a substantial amount of the business in this county is obtained over a period of one year, the rate will continue. No assessment can be made against the policyholder, and a dividend of 20 per cent, if earned, is returned to him. It is a legal reserve stock company, but is owned and operated by the Lumbermens Mutual Insurance Company. According to Ladd and Milne, the company offers this rate schedule only through their agency.

In summary, this committee chooses to recommend no one company for all the members. It is hoped that from

siderable importance, and a reasonable rate is desired.

The committee will gladly assist any member by allowing him to examine any of the data and all the letters that we have collected as a result of this investigation.

ALDEN B. GEORGE, M.D.

NEW HAMPSHIRE MEDICAL SOCIETY

DEATHS

COTTON — CURTIS B. COTTON, M.D., of Wolfeboro, died August 6. He was in his seventy-eighth year.

Dr. Cotton, the son of Joel F. and Elivna (Gilman) Cotton, was born in Moultonboro and graduated from the University of Vermont College of Medicine in 1888. He was a member of the New Hampshire Medical Society and the American Medical Association.

He is survived by his widow, a son and a sister.

ROWE — ARTHUR J. ROWE, M.D., of Penacook, died September 9. He was in his seventy-fifth year.

Born in South Barnstead, the son of Dr. James W. and Emma (Clark) Rowe, Dr. Rowe received his degree from Dartmouth Medical School in 1899. He was a member of the New Hampshire Medical Society and the American Medical Association.

He is survived by his widow, Mrs. Ida (Avery) Rowe, three brothers and a sister.

WAR ACTIVITIES

PROCUREMENT AND ASSIGNMENT SERVICE

The following release was recently received from the Washington office of the Procurement and Assignment Service:

The Directing Board of the Procurement and Assignment Service is pleased to announce that 95 per cent of the 1942 procurement objective of medical officers for the armed forces has already been met. Toward this total a number of states have supplied more than their share of physicians. Only a few states are lagging behind in their quotas, and it is from these states that the additional physicians needed during the current year should come.

The recruitment of such a large number of physicians in a few months is a remarkable achievement and another demonstration of the traditional patriotism and unselfishness of the medical profession. In this achieve-

ment, and particularly in those of its members who are "in service," the profession can justifiably take pride

The end, of course, is not yet. Increases in the armed forces will necessitate more medical officers, and additional demands will be made upon the profession for medical services in critical war-production areas. The Directing Board is convinced, however, that the physicians of this country will respond to future calls for service, whatever they may be, in the same splendid manner with which they have already volunteered for service with the armed forces.

of the Massachusetts Hospital Association, accepted the cup in behalf of the hospitals that participated in the observance.

On their return to Boston, Dr. Wilinsky and Mr. R. F. Cahalane, executive director of the Blue Cross, whose organization directed the program, were received by Governor Saltonstall, who stated: "It is a great honor for the hospitals of Massachusetts to be singled out among those of the entire country for this national award. It only serves further to confirm my belief that the hospitals of the Commonwealth will continue to administer in wartime, as in peacetime, to the needs of the civilian population."

The cup will remain the permanent property of the two organizations, and is on view at the Blue Cross headquarters, 230 Congress Street.

MASSACHUSETTS LABORATORY TECHNOLOGISTS RESERVE CORPS

To the Editor: At the suggestion of medical and hospital authorities of the Massachusetts Committee on Public Safety, the Massachusetts Technologists Reserve Corps—consisting of approximately three hundred and fifty women trained as hospital technologists—is being organized under the direction of a special committee. The one hundred and twenty-four emergency (casualty receiving) hospitals in Massachusetts will be assigned technicians up to the needs of each hospital, sometimes as many as three or four, for specialized work in the event of civil disaster; at present, there is a serious shortage of adequately trained laboratory technologists.

The organization of the corps will be somewhat like that of a military group, with state, regional and local heads. A chief medical technologist will be assisted by subordinate technologists, and technicians' aides will be enrolled in the near future. All members will wear standard insignia on their regulation laboratory uniforms.

The corps will be established by a special committee appointed by Dr. A. William Reggio, Medical Director of the Massachusetts Committee on Public Safety. Nine regional directors will be in charge of enrollment in their respective areas.

The personnel of the corps will be recruited from women who have had experience or are currently employed in hospitals, public-health laboratories, technical work for private physicians, industrial hygiene or pharmaceutical houses. They will be urged to spend two or three hours a week in refresher courses, unless they can demonstrate that they are already fully qualified for such work.

The regional directors, to whom inquiries concerning the corps should be addressed, are as follows:

- Region 1. Dr. Helen M. Scoville, 741 North Street, Pittsfield
- Region 2. Dr. Fred D. Jones, 20 Maple Street, Springfield
- Region 3. Dr. James S. P. Beck, 119 Belmont Street, Worcester
- Region 4. Dr. D. A. Nickerson, Salem Hospital, Salem
- Region 5. Dr. Charles F. Branch, 750 Harrison Avenue, Boston
- Region 6. Dr. Helmuth Ulrich, 99 Bay State Road, Boston
- Region 7. Miss E. K. Jones, Supt., Cape Cod Hospital, Hyannis
- Region 8. Dr. Isabel M. Wason, 101 Page Street, New Bedford
- Region 9. Dr. Edwin St. John Ward, Templeton

The co-operation of all physicians in the Commonwealth is requested to make this program effectual, and it is hoped that physicians who know of potential laboratory technicians will refer them to the proper regional directors.

DONALD A. NICKERSON, M.D., *Chairman*

TETANUS TOXOID IMMUNIZATION OF ADOLESCENTS*

Skin Reactivity, Allergy and Unfavorable Reactions

J. ROSWELL GALLAGHER, M.D.,† CONSTANCE D. GALLAGHER, B.A.,‡ AND GUSTAV G. KAUFMANN, M.D.§

ANDOVER, MASSACHUSETTS

PROPHYLAXIS against tetanus is of special interest to physicians who deal with adolescents. Members of that age group, because of their athletic and other activities, suffer frequent minor injuries, and the question of whether or not to give tetanus antitoxin prophylactically arises repeatedly; one must frequently choose between the dangers, discomforts and horse-serum sensitization of tetanus antitoxin and the possibility of tetanus following an apparently trivial wound. The present development of tetanus toxoid, reports of its efficiency in producing a protective level of antitoxin in the recipient's serum, and evidence that its administration is only rarely accompanied by unfavorable reactions appear to have solved, to a considerable extent, the problem of tetanus prophylaxis.

Inevitably, when the widespread use of a new prophylactic measure is suggested, attention becomes focused, and usually to an unreasonable extent, on the frequency and degree of unfavorable reactions produced by that agent. Hall,¹ in reporting the results of immunizing 2300 midshipmen, states that only 1 developed urticaria, only 2 had fever and malaise, and only 8 complained of sore arms after the first dose of alum precipitated tetanus toxoid; following the second dose, 1 case of anaphylactic shock, 4 cases of urticaria and 38 sore arms developed. During the following year, 793 men were immunized with a different preparation of toxoid, and an unfavorable reaction occurred in only 1 case. Whittingham,² in reporting the immunization of 61,000 men in the Royal Air Force, states that only 5 had malaise and fever and that 9 developed urticaria. A group of 186 allergic children, ranging from three to fifteen

years of age, were immunized by Peshkin,³ without any disturbing reactions: only 2 had a brief elevation in temperature.

The various objectionable features of tetanus antitoxin and the low incidence of unfavorable reactions from tetanus toxoid in such groups as those mentioned above, together with the apparent efficiency of toxoid in raising the serum antitoxin to a protective level, made us urge the parents of a group of adolescents under our care to have them actively immunized against tetanus. Extensive experience in the use of tetanus toxoid among adolescents is apparently lacking, and because of the frequency of unfavorable reactions from diphtheria toxoid in this age group, we approached our project more conservatively than the experience of others with different age groups seemed to justify.

Rogers⁴ has emphasized the desirability of this immunization for all allergic children, in whom the reports of Peshkin³ and Unger⁵ indicate that unfavorable reactions are uncommon. However, recent orders from the War Department⁶ suggest that allergic persons be skin tested and, if the skin test is positive, be given tetanus toxoid in divided doses; to be ultraconservative and also to determine the skin reactivity to toxoid in those persons both with and without an allergic history, we decided to test each boy in our series prior to each immunizing dose of tetanus toxoid. The results of these skin tests, the incidence of unfavorable reactions and the relations between these skin tests, reactions and various allergic states are reported.

METHOD

Permission to give tetanus toxoid was obtained from the parents of about 500 boys, who ranged in age from thirteen to nineteen years. Alum precipi-

§Assistant school physician, Phillips Academy.

tated toxoid in two doses of 1 cc. each was given; the interval between doses ranged from four to seven weeks. Prior to each dose, 0.1 cc. of a 1:10 physiologic saline dilution of the tetanus toxoid was injected intradermally, and after an interval of ten minutes, the skin reaction was recorded; in the rare cases in which the skin reaction was very strongly positive, the undiluted toxoid was given in divided doses—0.1, 0.2, 0.3 and 0.4 cc.—on four successive days. The degree of "sore arm" and of malaise, as recorded, was based on questions directed to each boy, and was obviously greatly influenced by the boy's personality as well as by our interpretation of his statements.

RESULTS

Table 1 presents the results of skin testing with a 1:10 physiologic saline dilution of tetanus toxoid that was injected intradermally before the first

TABLE 1. *Results of Skin Tests before Tetanus Toxoid Immunization.*

REACTION	NO. OF CASES	PERCENTAGE OF TOTAL
Negative	373	73.3

Total	509	

immunizing dose was administered. Eight per cent of the entire group showed a skin reaction measuring 10 mm. or more in diameter, and 3.7 per cent showed a strongly positive ($++$ or $+++$) reaction.

Table 2 lists the incidence of asthma, hay fever, previous tetanus antitoxin prophylaxis and hay fever or asthma prophylactic therapy in each group. The large percentage of boys who had

tetanus-antitoxin prophylaxis or allergy and only 5 of the 19 who had strongly positive skin tests gave a history of asthma or hay fever. The fact that 23 per cent of the $+++$ reactors had asthma is worthy of attention, but this seems less significant in view of the large number of those with asthma who had negative skin tests. It is of interest that of the 10 students who regularly received some sort of allergy prophylaxis, only 1 had an initial skin test with diluted tetanus toxoid greater than 20 mm. in diameter.

Table 3 shows clearly that the highest percentage of students having a history of various allergic states or previous prophylaxis always fell in the group with negative skin tests and that only relatively small percentages of each of these had strongly positive reactions.

The changes in skin reactivity following the inoculation of the first 1-cc. dose of tetanus toxoid and measured just before the administration of the second prophylactic dose were recorded. The entire group was not given a second skin test, but no boy whose first test was positive was omitted. Negative skin tests were recorded at both times in 318 cases; 109 others had approximately the same degree of reaction at both the first and second skin tests. In 10 cases, the first skin test measured less than 20 mm., and the second test was recorded as negative; second tests were recorded as $+$ in 10 subjects whose initial tests were negative. Three boys whose initial skin test was recorded as $++$ had at their second test a \pm reaction, and 9 whose initial skin test was \pm had a skin test of $++$ or $+++$ following their first immunizing dose of toxoid; in only these last 12 cases (2.6 per cent), was there a significant change in skin reactivity subsequent to the inoculation of an immunizing dose of tetanus toxoid. Of the 9 boys whose initial skin test was \pm or nega-

§This boy was given toxoid in divided doses

the first dose of toxoid, and that a moderate number of those who had similar complaints had negative skin tests.

Of the 12 boys admitted to the infirmary because of headache, malaise and fever, all of about twenty-four hours' duration, none had a positive skin test. Two boys, whose skin tests were negative, developed sterile abscesses at the site of injection a few days following both the first and second inoculations. Another, whose skin tests were strongly positive, developed giant urticaria after his first inoculation, given in divided doses; the second skin test was followed within four hours by the development of giant urticaria (which responded to adrenalin), and the second immunizing dose

inoculation indicated that these reactions were psychogenic.

Table 5 presents the incidence of unfavorable reactions among boys with a history of hay fever or asthma, or both, as compared with the reactions in those without history of allergy. It is obvious that there was no striking difference in the incidence of reactions in the two groups.

DISCUSSION

Our experience and that of many others clearly indicate that immunization with tetanus toxoid is a practical, safe and very desirable procedure; immunization at an early age and in combination with diphtheria antitoxin appears to be the method of choice, but our results indicate that the use of tetanus toxoid is satisfactory during adolescence.

The relatively high incidence of unfavorable reactions from diphtheria toxoid during adolescence and our belief that results obtained in other age groups should not be applied without careful investigation to adolescents were factors that interested us in the skin reactivity of this group to diluted tetanus toxoid. Because of the hesitancy of some physicians to give this prophylaxis to allergic persons, who obviously need it most, and because of recent War Department orders to proceed with caution in the immunization of all allergic persons, it is interesting that skin sensitivity to diluted tetanus toxoid is far from limited to members of the group having a history of allergy, and that although about 38 per cent of those having strongly positive skin tests had either asthma or hay fever, only about 14 per cent of those with asthma had strongly positive skin tests. Local and systemic reactions were no more frequent among those with positive skin tests to tetanus toxoid than among those who did not exhibit such sensitivity, but these results may have been affected by our procedure in giving divided doses to strongly positive subjects. A significant number (36 per cent) of boys with strongly positive skin tests gave no allergic history, and a considerable

number of those who had unfavorable reactions had both a negative skin test and a negative allergic history; it appears that neither skin reactivity to tetanus toxoid nor history of previous allergic manifestations is a reliable indicator of the

SUMMARY

Five hundred and nine boys ranging from thirteen to nineteen years of age were given two immunizing doses of tetanus toxoid without subsequent development of serious local or systemic

TABLE 5. Comparison of Unfavorable Reactions Occurring in Boys with and without a History of Allergy.

possibility of local or systemic reaction. Fortunately, no anaphylactic reactions were encountered in this group; one can only speculate whether anaphylactic or other reactions might have developed in any of the 15 boys whose skin tests were strongly positive had they been given full instead of divided doses of tetanus toxoid, but we do know that unfavorable reactions were negligible, except for 1 case of urticaria in this group. Four boys who had ++ skin tests were given full doses of toxoid: none of them had immediate unfavorable reactions, and none subsequently complained of sore arms or required admission to the infirmary, and only one complained of slight malaise. It seems necessary, before either the value of skin testing or the desirability of giving small divided doses to persons positive to the skin test can be determined, to investigate further the relation of anaphylactic or other severe reactions to skin sensitivity to toxoid and the incidence of severe reactions in strongly positive tests when toxoid is administered in full rather than divided doses. On the basis of our experience, the conservative and safe procedure in immunizing members of the adolescent age group is to precede the inoculation of tetanus toxoid by a skin test; little time or effort can be lost by this procedure, and until a more extensive experience with adolescents is available, conservatism is certainly commendable. Our results indicate that in only a small number of cases did initial mild skin reactions change to more strongly positive ones following the administration of the first dose of toxoid, and unless one is to be ultraconservative, a skin test prior to the second immunizing dose is hardly indicated.

reactions; the incidence of unfavorable reactions, however, was apparently higher in this group than among either younger or older subjects.

Strongly positive skin tests to diluted tetanus toxoid were recorded in 3.7 per cent of the group; 1 case of urticaria occurred, 2 sterile abscesses developed, and 12 subjects had sufficient malaise and fever to warrant infirmary care for twenty-four hours.

There is apparently little relation between known previous allergic states and skin sensitivity to diluted tetanus toxoid.

Neither skin sensitivity to diluted tetanus toxoid nor elicited previous history of allergic manifestations was found to be a reliable criterion on which to predict skin sensitivity or the development of unfavorable local or systemic reactions.

Fifteen of the 19 boys whose skin tests were strongly positive were given toxoid in four divided doses; no unfavorable reactions occurred in this group.

Until further experience with this age group is evaluated, it is suggested that skin tests with diluted tetanus toxoid be made prior to the administration of each immunizing dose.

ADEQUATE CLINICAL RECORDS—A PROFESSIONAL RESPONSIBILITY*

JOSEPH H. PRATT, MD †

BOSTON

IT is a fact as remarkable as it is disturbing that physicians on the whole do not realize the value of medical records of the patients under their care. This neglect is all the more surprising because leading medical teachers have by precept and example emphasized the value of the clinical history and of careful observations made at the bedside. The injunction to observe, to record and to analyze has often been made. It is necessary to have as good medical records in a small hospital as in a large one because the patient presents the same problems in each; he is entitled to thorough study and his record should be written promptly, accurately and completely.

Dr. Malcolm T. MacEachern,¹ director of hospital activities of the American College of Surgeons, states: "Prior to the commencement of the hospital standardization program in 1915, only a limited number of hospitals in the United States, less than one hundred, kept medical records of an acceptable type. The remainder of the hospitals had scant information other than that found in the nurses' notes." The minimum standard established twenty four years ago by the American College of Surgeons and efforts to secure its enforcement have resulted in some improvement, but much remains to be done. Clause 4 of the minimum standard relates to medical records; it states, "that accurate and complete records be written for all patients and filed in an accessible manner in the hospital." It defines a complete medical record as one that includes identification data, complaint, personal and family history, history of the present illness, physical examination, special examinations, provisional or working diagnosis, medical or surgical treatment, gross and microscopic pathological findings, progress notes, final diagnosis, condition on discharge, follow up and, in fatal cases, autopsy findings. Unfortunately, many hospitals—even some of those approved by the American College of Surgeons—keep records that are far from satisfactory. The fault lies in the failure of the members of the medical staff of the hospital to become "record conscious." Much of the blame can be traced back to the clinical teachers in the medical schools, who did not instill into the minds of their students the necessity of keeping detailed records if they are to do justice to themselves or to their patients.

Hippocrates,² in the dawn of history, recorded as accurate observations as were possible at that time and made daily progress notes in acute cases. An example, selected almost at random, is Case 4 from the 26 cases he collected for his third book on epidemics.

In Thasus, Philistes had headache of long continuance, and sometimes was confined to bed with a tendency to deep sleep, having been seized with continual fevers from drinking, the pain was exacerbated, during the night he at first became hot. On the first day he vomited some bilious matter, at first yellow, but afterwards of a verdigris green color and in greater quantity, formed feces passed from the bowels, passed the night uncomfortably. On the second day, deafness, acute fever, retraction of the right hypochondrium, urine thin, transparent. On the third in an uncomfortable state. On the fourth, convulsions. All the symptoms exacerbated. On the fifth early in the morning, died.

This record presents clearly and objectively, four hundred years before the birth of Christ, what appears to be a fulminating case of meningitis. There is great need today of cultivating this ancient diligence of Hippocrates in the recording of medical cases.

Laennec, the greatest name in medicine after Hippocrates, based his epoch making work in auscultation on his records of detailed physical findings and his autopsy notes in diseases of the chest.

As an illustration of how bad records are today, I cite the following recent experience. I saw a patient on the eighth day of her illness and made the following note:

February 17, 1942 Mrs S. K., aged 31. Complains of frequent chills and fever.

Present illness. Onset with a sore throat on February 10. The next day cough began and she had a tight feeling behind the sternum. On the night of February 12, she awoke feeling very hot, she took her temperature and found it to be 102.5°F. Doctor called the morning of February 13, examination of the chest was negative, but the temperature was not taken. The patient raised much greenish sputum on the following day, previously, the cough had been dry. She had a series of shaking chills lasting half an hour or so beginning on the night of February 14, followed by a sense of great heat. On February 15, the temperature reached 101.5°F. Yesterday morning about 7 o'clock, it was 100°F. At 11 30, it was 98.6°F. At about 4 p.m., the temperature was 103.5°F. A shaking chill occurred in the middle of the night.

Examination of the chest was negative. Although the oral temperature at the time of examination

*Read at the twenty eth meeting of the New England Hospital Assembly Boston March 11, 1942.

†Professor of clinical medicine, Tufts College Medical School, physician-in-chief, New England Medical Center.

was 101.1°F., the respirations were only 16. There was no leukocytosis, and the urine was normal. It was evident that this was an unusual case that demanded careful study for a correct diagnosis. The patient was sent to an excellent small hospital in a neighboring town where resident physicians, a full-time roentgenologist and a pathologist were on the staff.

The history of the present illness, taken by a salaried resident physician, was as follows: "Chief Complaint: Chills and fever. Burning on urination. Date of onset week today, which began as a heavy chest cold." No attempt at a record would have been better because two of the three state-

be the correct diagnosis. The resident, of course, learned nothing from his so-called "study" of the case. Because this history was the worst I think I have ever read in my experience of forty-seven years, I interviewed the young man and found that he had graduated from an unrecognized school, where he had had no practical instruction or experience in case taking. He had served an internship in a large hospital, where he had had a large experience in case taking, but his clinical histories had been accepted without correction and his records had never been supervised by the attending physicians.

A pleasing contrast to the unsatisfactory state of medical records in many hospitals of New England today is presented by an examination of the medical records of the Massachusetts General Hospital made over a hundred years ago (Fig. 1).

This hospital was opened in September, 1821. Since that date, the records have been carefully preserved. The first 50 cases were bound to form Volume 1 of the medical records. For about a hundred years thereafter, each series of 50 cases was bound in a separate volume. These early case reports are worthy of study. The history of the very first case was written out in detail (Fig. 2). The careful penmanship attests to the value attached to the clinical record. I have read that the physician's notes were copied for the official record by the hospital apothecary, who wrote a fine hand. James Jackson was the physician-in-chief. His opinion of the worth of medical records is attested by his own statement:

It has been the practice at the Massachusetts General Hospital, in the medical department, to note the state of the patient every day, in acute cases, as our records show. It has been our intention to inquire into the state of all the functions in the beginning of each case, and more or less fully from day to day. But we have been willing to diminish the labor of our records by mentioning only the functions which manifested disease, while oftentimes we made no records of those which appeared healthy. Unless it was certain, however, that this course was uniformly pursued, it is obvious that there must be some uncertainty in any given case, whether something had not been omitted. There is no doubt that our negligences have been so frequent that our records cannot be relied on, except for what is positively stated. Nor can we say that our inquiries have been sufficiently full originally. We have often failed in learning and still oftener in stating the previous histories of our patients. . . . In the first years we were the most deficient, but we have made our observations with more and more care as we have proceeded.

He wrote these words in his classic report on typhoid fever,³ communicated to the Massachusetts Medical Society in 1838.

Where did Dr. Jackson get his conviction of the significance of hospital records, which possessed

ments made were false and hence misleading: the patient had had no burning on urination, and she had not had a chest cold.

On inquiry, I found that there was no supervision of this resident's records. The history as I have given it stands as the official record. The case history as given by me was typical of virus pneumonia, a disease that has only recently been recognized and presents a striking and characteristic clinical picture. This was subsequently proved to

him when he first took charge of the medical work at the hospital in 1821.² Doubtless, the answer is, From his teachers in Great Britain, where he "walked" the hospitals of London and Edinburgh in 1800. It seems evident that the case records of these British hospitals must have been good and

diseases and the present illness, we have the testimony of James Jackson⁴ that Louis made and recorded more thorough observations than any of his predecessors

He noted the actual phenomena present at his examination, depending for this not only on the statement of the patient, but on his own senses, his eyes, his ears, and his hands—he was not satisfied with noting the functions, in which the patient complained of disorder, but examined carefully as to all the functions, recording their state as being healthy or otherwise, and even noticing the absence of symptoms which might bear on the diagnosis

I have heard Osler refer to Louis as the patron saint of the Massachusetts General Hospital, but it was not the influence of Louis that first led James Jackson to keep good records from the opening of the hospital. This is a known fact, since Jackson has left on record the statement that he first learned of Louis's work in 1830. This was nine years after the opening of the hospital. His later debt to Louis, he freely acknowledged. The value of making and recording the physical examination in the manner outlined above, was taught him by Louis. In the first case admitted to the hospital, there was not a single entry on the objective symptoms and signs presented by the patient at the time of his entry, the record dealing solely with the present and past history. This defect was soon remedied, and it was not long before careful notes were made of the objective findings

In the summer of 1833, James Jackson, Jr, then twenty three years of age, returned to Boston after nearly two years of study in Paris, carried on chiefly under the direction of Louis. On the morning of October 15, 1833, young Jackson went to the Massachusetts General Hospital, where he examined a patient ill with typhoid fever, who had been admitted on the previous evening to his father's service, and recorded the following notes on the case (I give them in full as they furnish convincing evidence that the quality of this medical record, made one hundred and eight years ago, and the care and thoroughness of the observations were of a high order)

October 15, 1833—S K, aet. 32, unmarried, eyes, hair and complexion dark, maid servant, born in Salem. Entered the hospital last evening ill since seventh instant, perfectly well before, on that day headache, distress and pain in limbs, anorexy, weakness, obliging her to go to bed. Since then she has had bad taste in mouth, no soreness of throat, nor dysphagia, thirst, anorexy, nausea after taking too much liquid, but not at other times, diarrhoea from the first, four or five dejections a day, urine not observed, cata mena on 10th, lasting one day (they had occurred in order the week preceding), no chills, occasional

FIGURE 2

that he took them as a model when the Massachusetts General Hospital was opened. Additional evidence of the importance attached by Scottish hospital physicians to clinical records in the first half of the last century was the custom, introduced by them, of giving the name of the clinical clerk who made the record when they published the notes of the case in a medical paper.

It is of interest to discover and give credit to the physician who first taught and practiced the approved modern plan of making and recording a thorough clinical history and complete physical examination. I am convinced from my reading that this honor belongs to the great French physician, Pierre Charles Alexander Louis. In addition to a careful history of the family, the past

heat and sometimes sweat at night; no cough; nor dyspnoea, or very little of these; no pain in chest, nor palpitation; headache and dizziness; tinnitus aurium and deafness; no epistaxis; no sleep; some delirium. On the 10th she had the following: Rx. hydr. subm. jalap. 33 gr. viii—misce. After this some castor oil; and, the dejections, continuing too frequent, she had fifteen drops of tinct. of opium. After this she had not any important medicine.

The above details were partly from the physician who had attended her.

Now, October 15th, morning; — countenance, as well as mind, very stupid; memory treacherous; cannot tell how long she has been ill, though clear and positive as to existence, or non-existence of certain symptoms; features still, eyes fixed, looking melancholy; face pale or sallow, and evidently emaciated; since her entrance (five p.m. yesterday) no vomiting; great thirst of which only she has complained; two dejections, very watery, not dark, nor painful, quite offensive to smell, one of them a pint; through the night restless and watchful, and probably delirious, though silent, for she arose from bed and went to table for drink in absence of watcher, though she has seemed too feeble to rise up. Lips slightly dry; tongue dry, enlarged, protruded partially, a thin, brown coat over part of lobes; some soreness of gums, which have a white coat and give out a mercurial fetor; abdomen not swollen, nor painful, but a little tender on pressure at epigastrium; some small rose pimples on abdomen, but no sudamina; spleen not felt; skin hot and dry; pulse varies from 112 to 120, small, not soft; resp. 21, not difficult; no dilatation of alae nasi, but slight noise in nose; lies on right side.

How shall the pressing problem of obtaining adequate medical records in small hospitals, as well as large, be solved? Various means have been suggested and applied with success. It is essential that the medical staff be convinced of the necessity of good medical records; this is a matter of education. The reasons for keeping case records have been well stated by Musser⁵ as follows:

Records of cases should be kept for obvious reasons. The habit compels a general survey of the case, and tends to prevent oversight in the examination. It naturally aids in the training of the powers of observation. It teaches a precision in the narration of cases. The memory is aided by repetition and by lack of haste in ascertaining phenomena. The data are on record for more mature reflection, and to aid in the study of the literature of similar cases. The record is of value in case the patient returns for advice after a lapse of time. It may be of medico-legal value. The mental effect on the patient is good, for the taking of notes requires time and accurate, studied observation. In case it is desired to study a large number of cases, records are scientific data.

No patient is adequately cared for by the hospital physician until all information bearing on the case has been elicited and recorded. To do less is to neglect the patient. If the physician realizes this, he can no longer offer the excuse that he is too busy to write notes, for this is tantamount to

saying he is too busy to care properly for his patients. Notes do not have to be long to be adequate: a few sentences dictated at the bedside or at the operating table may be worth more than a page written the following day. Every hospital should, if possible, provide a secretary or a dictaphone.

In the preparation of the following suggestions MacEachern's¹ writings have been helpful.

1. Physicians might be convinced of the value of good clinical records if they were required on accepting an appointment to the medical or surgical staff, to sign a statement that they assume responsibility for seeing that all the records of patients under their care are written promptly and completely. This responsibility cannot be delegated to interns or residents.

2. Residents, if properly trained, are of great aid in providing good records, but their work should be supervised by the attending physician, who should always make and record his own observations. Otherwise, it is the record of the resident and not fair to either the physician or his patient.

3. A medical-records committee should be appointed. It is the duty of the chief-of-staff to see that this committee is active and efficient. It should review all records regularly, preferably weekly, and promptly refer back unapproved records to the responsible physician.

4. A medical-records librarian should be provided. She can judge the records quantitatively, if not qualitatively, and can furnish much aid to the medical-records committee.

5. Evaluation of the medical record should first be done by the attending physician. MacEachern says that the practice is increasing of having the attending physician sign a statement reading as follows: "This is to certify that I have carefully reviewed the attached record, . . . and to the best of my knowledge, I find it accurate and complete." He continues:

To do its work thoroughly and impartially the medical records committee must have the authority of the medical staff to make frank and unprejudiced appraisal of each record. It also has the responsibility of reporting to the medical staff, at each meeting regarding deficiencies. Medical records will only attain a proper standard of quality if they are actively reviewed in every hospital in a critical, constructive, and unbiased fashion at stated regular periods, and reports made systematically to the administration and the medical staff.

6. A medical audit may be carried out. This is based on an analysis of the discharge records of all patients and was devised by Dr. Thomas R. Ponton⁶; its introduction was aided by the Association of Record Librarians of North America.

I have observed its successful employment at the Thayer Hospital, Waterville, Maine, where it was introduced by Dr. Frederick T Hill. It is an additional aid in obtaining good medical records and may prove worthy of adoption by all hospitals.

During the last few years, earnest efforts have been made by laywomen serving as record librarians, as their published papers indicate, to devise means for making hospital physicians record conscious. Shades of Hippocrates, Louis and James Jackson! What a shock to these pioneers it would be to learn that the physicians of the present generation, who pride themselves on the high position attained by scientific medicine, have neglected the very foundations on which scientific

medicine rests—namely, the careful observation and recording of facts obtained by the unaided senses—the eyes, the ears and the hands—of the examiner. Physicians in small hospitals often lament the lack of laboratory facilities for special tests, but they still neglect the all important methods available to all.

THE DRUG THERAPY OF MIGRAINE HEADACHE*

LOWELL S. TROWBRIDGE, M.A.,† THÉODORE J. C. VON STORCH, M.D.,‡
AND MAJOR MERRILL MOORE, M.C., A.U.S.§

BOSTON

UNTIL recently, migraine headache has been most difficult to control. However, since the advent of ergotamine tartrate, this drug has been effective in aborting or terminating 90 per cent of the attacks in 600 cases.¹ In spite of such encouraging results, older and nonspecific drugs continue to be used by those suffering from migraine, probably because of ignorance on the part of the lay public concerning the existence of ergotamine tartrate. To compare the results obtained by specific (ergotamine tartrate) therapy and nonspecific therapy, the effects of various medications used by 200 patients were analyzed in terms of the patients' evaluation of the various drugs. Ergotamine tartrate was employed in the Out Patient Department of the Boston City Hospital. The other drugs were used by the patients on their own initiative or were prescribed by physicians outside the hospital. All the observations are subjective and were elicited directly from the patients.

The diagnosis of migraine was determined according to criteria previously specified by one of us.² The patients were asked to name the drug or drugs used by them to relieve their headaches and to evaluate the relief obtained.

The analysis of patients' reports on their experience with various therapies included only drugs that, in our opinion, had been used by the patient long enough to permit him to evaluate

them accurately. There were two steps in the analysis of the data: classification of drugs in groups according to their type or site of action, and a compilation of the number of patients who had used drugs in each group with their subjective opinion of the result of such use. Most patients had employed several—in some cases, as many as ten drugs—in their search for relief.

There were eight groups comprising forty-eight different drugs that had been tried from time to time. Individual patients had used these drugs for

various periods, ranging from a single trial to the prolonged use of a drug for more than fifty doses. The therapeutic results, as reported by the patients, are summarized in Table 1.

The group of vasoconstrictors included the cerebral vasoconstrictor, caffeine,³ and the dural vasoconstrictor, ergotamine.⁴ Both seemed to be highly effective, although the small number of patients who had tried caffeine (6 cases) precludes an

*From the Neurological Unit, Boston City Hospital and the Department of Neurology, Harvard Medical School.

†Clinical psychologist, Washington Hospital.

‡Formerly assistant visiting neurologist, Boston City Hospital and instructor in neurology, Harvard Medical School.

§Associate in psychiatry, Harvard Medical School and assistant visiting physician, Boston City Hospital (on leave of absence).

adequate evaluation of this alkaloid. Eighty per cent of those using ergotamine reported complete relief from the migraine attacks. Because some used the drug orally and others by hypodermic, the percentage relieved is a composite of the relief obtained by the less effective oral and highly effective parenteral routes.⁵

The narcotic group consisted of morphine, pantopon, codeine and scopolamine. Morphine and codeine were most effective, the former being reported to be completely effective in 59 per cent of the patients who used it. However, relief was conditional on the ability of the narcotic to cause sleep or to depress the patient's general physiologic state.

The barbiturates included phenobarbital, Pentobarbital and Allonal. Phenobarbital helped 16 per cent of the patients who tried it.

Under analgesics were classified such drugs as acetanilid, acetylsalicylic acid, amidopyrine, phenacetin and various proprietary remedies containing these substances. Acetylsalicylic acid was successful in giving relief to 10 per cent of the 186 patients assumed to have tested it adequately.

Among the drugs acting on the gastrointestinal system were dilute hydrochloric acid, sodium bicarbonate, Seidlitz powders and various proprietary preparations; Seidlitz powders were the most effective of this group, 18 per cent of its users reporting it helpful. These remedies did not seem to act directly on the headache, but rather relieved the distress due to nausea and vomiting, so that their value in alleviating discomfort from migraine is secondary if not open to question.

Of the bromides, including Bromo-Seltzer and the various bromide salts, Bromo-Seltzer was slightly more helpful than the other drug preparations, but as a whole this group may be said to be relatively ineffective in migraine therapy.

Although not many patients in this study were treated with endocrine substances, the results are included as evidence concerning the casual use of endocrines for migraine. Thyroid, Theelin, Progynon, Hormatone and anterior pituitary extract were administered. Only 1 patient was satisfied with the relief obtained. This patient received pituitary extract. Obviously, these observations are not sufficient to warrant any comment other than that they reflect the results usually obtained from casual application of endocrines in office practice.

Because of the widespread advertising of proprietary medicines described as "headache remedies," it is remarkable how few migraine sufferers have tested them. Of the 29 who did, only 4 per cent obtained adequate relief.

In addition to the cases analyzed above, various drugs acting on the autonomic nervous system were used without success. Seven patients used vasodilators, but none were adequately relieved. Laxatives were reported as fairly helpful by 4 of the 7 patients trying them.

SUMMARY

It may be said that many misinterpretations are made in the evaluation of headache remedies, especially in the therapy of migraine. In this study, there was considerable difficulty with some of the patients in determining whether the particular headache treated by a given drug was actually migrainous, although the patient suffered from migraine attacks at certain times. Side actions of the various drugs may have afforded some secondary relief without affecting the headache itself.

The greatest relief was from drugs in the vasoconstrictor group, consisting mainly of favorable reports on the use of ergotamine tartrate by 80 per cent of its users, in spite of the unpleasant and pronounced side actions. This re-emphasizes the observation that drugs causing vasoconstriction of the branches of the external carotid artery⁶ are by far the most successful in terminating or aborting migraine headaches. Analgesics were tested most frequently by the greatest number of cases, but with comparatively unsatisfactory results.

Perhaps newer therapeutic methods, such as oxygen inhalation,⁷ vitamin B₁ therapy⁸ and arterial ligation⁹ will prove effective in the future. Until such time, ergotamine tartrate remains the most effective means of terminating a migraine attack.

FIRST LIEUTENANT KNOWLES B LAWRENCE, MC, A US,* AND HOWARD M CLUTE, M.D †

BOSTON

IN RECENT years many surgeons have accepted the principle of early operation as the safest method of handling acute cholecystitis. This means that surgery in many such cases will be done as soon as the patient's condition permits and before time has allowed elaborate laboratory studies. It is frequently necessary, therefore, to differentiate clinically between acute cholecystitis and certain other upper abdominal conditions that may be more suitably handled by conservative means. Our recent experience shows that certain intrinsic diseases of the liver may simulate acute cholecystitis so closely that clinical differentiation is difficult, if not impossible.

The pathologic changes in acute cholecystitis in the early period—that is, the first twenty-four to seventy-two hours after onset—are essentially mechanical in character, as has been demonstrated by a number of investigators at this clinic¹ and elsewhere.^{2,3} The process starts with the blocking of the cystic duct, usually by an impacted gall stone. The resulting edema and venous stasis in the wall of the cystic duct plus obstruction to the outflow of gall bladder contents set up a vicious circle resulting in a high degree of vascular and lymphatic block of the entire gall bladder. Local ischemic necrosis of the gall bladder wall may then take place, with perforation resulting if the area involved is large enough.

Changes such as these should, and usually do, produce a fairly standard clinical picture. Initially there is local colicky pain, acute or subacute in onset, as the gall bladder attempts to force an impacted stone through its too narrow cystic duct. Pain of such origin commonly radiates also around the right lower costal margin to the right scapular region. Nausea and reflex vomiting may occur in this stage. As the circulatory changes progress the gall bladder becomes distended, its musculature is less able to contract, so that the colicky pain is superseded by an intense dull ache, a visceral pain due to overstretching of the peritoneal coat. The viscus may then be palpable as a tense and very tender mass below the right liver margin. This is the stage in which the patient is often seen by the surgeon, it may occur a few hours to a few days after onset. Despite the usual absence of

bacterial inflammation, there is characteristically a slight rise in temperature and pulse rate and a moderate polymorphonuclear leukocytosis. Later in inflammatory reaction of the serosa may be manifested by tenderness and muscle spasm over the gall bladder region. Perforation of the gall bladder with peritonitis is usually obvious to the examiner as an acute surgical emergency.

Thus, when one considers acute cholecystitis in the light of the pathologic process, it becomes apparent that certain diseases of its neighbor, the liver, might well simulate its clinical picture. The following morbid mechanisms might be postulated: necrosis in a tumor nodule growing more rapidly than its blood supply, thus causing a considerable reaction on the peritoneal surface, stretching of Glisson's capsule by an underlying hemangioma, abscess or echinococcus cyst of the liver, and a more diffuse hepatic inflammation causing pain through both the above mechanisms plus possible affection of the visceral sensorium—for example, a fulminating acute hepatitis or yellow atrophy. Fever, leukocytosis, systemic debility or reflex gastrointestinal symptoms may be as commonly associated with certain of these conditions as with acute cholecystitis.

At the Massachusetts Memorial Hospitals we have encountered several cases of intrinsic liver disease which simulated acute cholecystitis so closely that the diagnosis was often difficult and uncertain. These cases, with comments on their diagnosis and management, are as follows:

CASE 1 A 56-year-old white woman entered the hospital complaining of right upper-quadrant pain of 5 days duration. Fifteen years and 2 years previously she had had attacks of pain and indigestion and x-ray films were said to have shown trouble with the gall bladder. Similar symptoms set in 6 weeks before admission. She had had some vomiting also and diarrhea without blood. Five days before admission severe right upper-quadrant pain began with radiation to the right posterior shoulder region, mild chills and fever. There was a 34 pound weight loss in 3 months.

On examination the patient appeared in acute pain. A tense, rounded, very tender mass, the size of a small fist, was felt in the gall bladder region. The liver edge could be palpated 5 cm below the right costal margin, rounded and slightly tender. On rectal examination a hard polypoid mass involving the anterior rectal wall and invading the pararectal tissues, an obviously malignant neoplasm, was found. The admission temperature was 102.4°F, the pulse 100, and the white-cell count 15,000, with 84 per cent polymorphonuclears.

Laparotomy was performed shortly after admission, and the mass felt preoperatively was found to be a hard tumor

*Assistant in surgery, Boston University School of Medicine, and assistant surgeon, Massachusetts Memorial Hospital (on leave of absence).

†Professor of surgery, Boston University School of Medicine, surgeon-in-charge, Massachusetts Memorial Hospital.

nodule imbedded in the liver. Just medial to it lay the virtually normal gall bladder. There were multiple tumor nodules throughout the liver, and a biopsy of one of these showed an anaplastic, rapidly growing metastatic adenocarcinoma. The patient died 6 weeks later.

The clinical picture in this case so closely simulated that of acute cholecystitis that early operation seemed the wiser course, despite the knowledge preoperatively of the patient's carcinoma of the rectum. Had the routine rectal examination been omitted, as it is at times, unfortunately, the case for acute cholecystitis would have been even stronger. We surmise that the symptoms and signs in this case were due to necrosis within the large tumor nodule lying just to the right of the gall bladder.

CASE 2. A 67-year-old white man, a physician, was admitted because of bowel symptoms and weight loss. Five years previously a resection of 12 cm. of transverse colon had been performed for a "malignant polyp" at another hospital.

The physical examination was essentially negative. The patient was studied in great detail without definite findings. Three weeks after admission he developed rather suddenly a severe right-upper-quadrant pain with tenderness and spasm in the right subcostal region. The liver edge was palpable and possibly somewhat irregular. The temperature was 99.6°F. and the white-cell count 11,300, with 87 per cent polymorphonuclears.

A previous cholecystogram had demonstrated a probable chronic cholecystitis and cholesterosis. No stones were seen. In view of the clinical picture at this time a diagnosis of acute cholecystitis was considered, but the probability that the symptoms were due to metastatic liver disease was so strong that operation seemed unwarranted. The symptoms subsided somewhat, and the patient died several weeks later of general carcinomatosis, including the liver, and terminal pneumonia.

CASE 3. F. B., an 83-year-old white man, was admitted to the Massachusetts Memorial Hospitals on April 16, 1942, complaining of severe right-sided abdominal pain for 4½ days' duration. At first this pain was felt in the right midabdomen, then 24 hours later worked up into the right upper quadrant and beneath the costal margin, where it persisted as a fairly constant, severe aching pain. The pain did not radiate, but was severer when the patient breathed deeply or moved about.

During the previous year the patient had become increasingly constipated and had experienced frequent bouts of painless vomiting lasting a day or more, usually occurring when he was constipated. There was no pain associated with this. He had been passing gas satisfactorily up to the time of admission. There was no history of chest pain. The patient's health prior to this trouble had been reasonably good for his age. He had had a suprapubic prostatectomy for benign prostatic hypertrophy 3 years previously.

Examination showed an emaciated elderly man in obvious pain lying on his left side with the legs drawn up. The rectal temperature was 101°F., the pulse 92, and the blood pressure 118/80. Marked generalized arteriosclerosis was noted. The heart and lungs were normal for the patient's age. The abdomen was slightly distended and was resonant throughout. It was generally soft ex-

cept for definite spasm of the right-upper-quadrant muscles near the costal margin and definite tenderness over this same area. A poorly defined mass, possibly 6 cm. in diameter, could be felt and percussed in this area and seemed to come from beneath the costal margin. Peristalsis was somewhat hyperactive throughout the abdomen.

The white-cell count was 10,200, with 78 per cent polymorphonuclears, and the red-cell count 3,190,000, with a hemoglobin of 64 per cent. The nonprotein nitrogen was 43 mg. per 100 cc., and the icteric index 10. Urinalysis revealed a trace of albumin, many white cells and rare red cells. The urinary diastase was less than 4 units. A flat x-ray film of the abdomen showed no opaque calculi. The colon appeared distended with gas. A barium enema done the following day showed a diverticulosis and a diverticulitis of the sigmoid and colon without obstruction.

A provisional diagnosis of acute cholecystitis was made. It was thought that the process was localized and would probably subside with conservative treatment. In view of this and the patient's extreme age, operation was deferred.

The patient was given sulfadiazine by vein and by mouth and a sufficient quantity of intravenous fluids. He continued to run a low-grade septic course with the temperature ranging between 99.6 and 102°F. (rectal). The white-cell count varied between 11,000 and 17,000. The pain and tenderness persisted. The right-upper-quadrant mass became larger and considerable fluid accumulated in the abdomen. The patient was thought to have developed a pericholecystic abscess.

Operation was therefore performed, with intent to drain the gall bladder, 8 days after admission. The finding, however, was an enlargement of the liver by irregular infiltrations with yellow tumor tissue. The biopsy diagnosis was primary hepatoma. The gall bladder was not inflamed. The patient went downhill rapidly and died 36 hours later.

Autopsy revealed massive enlargement of the liver by primary hepatoma, which in two places had grown into the stomach wall. The gall bladder showed no disease.

This case closely resembled one due to acute cholecystitis. Even in retrospect, no direct clinical leads to the correct diagnosis are apparent.

CASE 4. A 36-year-old Negro entered the hospital complaining of severe retching, vomiting and malaise of 3½ days' duration. He denied real pain—only a slight upper-abdominal soreness. The vomitus was reflex rather than obstructive in type, and the patient's evacuations continued fairly normally. He dated his illness from the inhalation of fumes from an accidentally broken fire-extinguisher bulb containing carbon tetrachloride. Eighteen months before entry, on a previous admission for gonorrheal epididymitis, the liver edge had been felt three fingerbreadths below the costal margin; the patient was given 40 gr. of sulfanilamide daily for 6 days for his gonorrheal infection. He was known to have been a chronic alcoholic for several years. There was no history of definite gastrointestinal symptoms prior to the present illness.

On examination the temperature was 102°F., and the pulse 100. The patient was acutely ill, groaning with pain and rolling from side to side with the thighs flexed on the abdomen. The upper two thirds of the abdomen, particularly on the right side, was nearly boardlike and exquisitely tender. This splinting, plus a well-developed musculature, prevented satisfactory palpation or even percussion of the upper abdomen. The liver margin could

not be palpated. Jaundice was not apparent, as the patient was a Negro and was seen after nightfall. The white-cell count was 31,000. The urine contained a trace of bile. X-ray films of the abdomen and diaphragmatic area showed the liver somewhat enlarged, but no free gas or other abnormalities. Despite an atypical history, it was believed that the signs were those of an acute upper abdominal peritonitis possibly from a perforated gall bladder or peptic ulcer, and that immediate operation was imperative.

On opening the abdomen an acute hepatitis with free bile stained peritoneal fluid and toxic regional lymphadenitis was found. A biopsy specimen from the liver was diagnosed acute hepatic necrosis (central type). Following the operation the patient declined rapidly and died 1½ days later. An autopsy revealed a hemorrhagic central necrosis of the liver, probably due to carbon tetrachloride poisoning, toxic nephrosis and pulmonary edema.

This case illustrates the well known fact that certain cases of acute hepatitis present a clinical picture difficult to differentiate from acute surgical conditions of the upper abdomen. Knowledge of this combined with the history of exposure to a hepatotoxic drug should make the surgeon doubly wary.

In studying the literature, we were able to find little on the subject of diseases of the liver simulating acute cholecystitis. However, the following conditions, which at times have produced similar clinical pictures, are mentioned, ruptured hemangioma, spontaneous rupture of the liver and

spontaneous subglissonian hemorrhage, simple cysts of the liver with or without rupture, tuberculoma and gumma, echinococcal cyst, amebic abscess, pyogenic abscess and neoplasms of the liver, primary or metastatic.

CONCLUSIONS

Acute hepatic disease may simulate acute cholecystitis as to sudden onset, low fever, an elevated white cell count and a tender mass in the right upper quadrant.

A history of exposure to a hepatotoxic drug should lead one to consider the possibility of acute yellow atrophy.

The clinical picture of acute cholecystitis may also be simulated by primary or metastatic cancer of the liver, particularly when secondary hemorrhage or necrosis has occurred. A history of previous malignancy should make one suspicious of this.

These and other intrinsic diseases of the liver are occasionally difficult to differentiate from acute cholecystitis.

PRIMARY CARCINOMA OF THE APPENDIX ASSOCIATED WITH ACUTE APPENDICITIS

Report of a Case

EDWARD L. YOUNG, M.D.,* AND FIRST LIEUTENANT STANLEY WYMAN, M.C., A.U.S.

BOSTON

PRIIMARY carcinoma of the appendix must be differentiated from carcinoid of the appendix and carcinoma of the cecum. Failure to distinguish between these conditions has led to an unfortunate confusion in the literature.

Carcinoid is a disease usually found unexpectedly by the pathologist. Eighty-two per cent of cases occur in females,¹ and the greatest incidence is found in the third decade.² Such cases comprise less than 0.4 per cent of all intestinal cancers.³ Carcinoids are usually firm ovoid tumors, often yellow, located near the tip of the appendix. They are composed of cells originating from the Kulchitzky cells in the bases of Lieberkuhn's glands. Because the cells contain silver reducing granules,

the tumors are often called argentaffinomas. They resemble basal cell epitheliomas in that they often form sheets or islands of cells with occasional mitoses. In general, they act as benign tumors, but metastases to the liver and regional lymph nodes have been reported.

Carcinoma of the cecum most frequently takes the form of a large fungating mass that may occlude the lumen of the appendix or infiltrate its base, at times giving rise to symptoms of appendiceal obstruction. Many cases of carcinoma of the cecum are reported in the literature, in contrast to primary carcinoma of the appendix.

True carcinoma of the appendix is primary in that organ and is usually colloid in type.⁴ It causes no specific signs or symptoms, but at times the patient may give an atypical history of appendicitis or may have recurrent attacks of right lower

†Formerly, Junior Officer, Faulkner Hospital.

quadrant pain. It may make itself known as a mass in the abdomen, cause a generalized peritonitis by perforating the bowel or obstruct the lumen of the appendix. The literature of the last ten years contains many reports of carcinoma of the appendix, but close examination reveals only 4 cases of apparently true primary carcinoma—Darnall and Kilduffe,⁵ Blumenkopf,⁶ Heine⁷ and Frauenthal and Grausman.⁸

CASE REPORT

A 36-year-old married man entered the Faulkner Hospital on June 24, 1940, complaining of pain in the abdomen. Two weeks before entry, he had an episode of pain in the abdomen preceded by soreness low in the back. Abdominal pain lasted 4 or 5 days and was accompanied by fever, but there was no nausea or vomiting. A physician told the patient that he had mild appendicitis and that if he had a recurrence he should be operated on. On the day before entry, the patient noticed slight twinges of pain in the right lower abdomen, but he went to bed and slept well. He awoke with a sensation of soreness in the lower abdomen. During the course of 2 hours, the pain increased rapidly in severity, and by 11 a.m. the patient was almost doubled up with crampy abdominal pain. There was no nausea or vomiting, and the bowels moved normally on the day of entry. There was no pain or burning on urination, and no hematuria, pyuria, recent cold or pain in the chest. The past and family histories were irrelevant.

Physical examination revealed a well-developed and well-nourished man lying in bed with the legs bent. The height was 5 feet, 8 inches, and the weight 200 pounds. The temperature was 101°F., the pulse 74, and the respirations 20. The tongue was coated, and the throat slightly injected. The heart and lungs were normal. There was no costovertebral tenderness. The abdomen was flat, and no organs or masses were palpable; there were no hernias. Slight spasm was apparent in the right lower quadrant, with very definite acute tenderness in a sharply localized area over McBurney's point. Pain and rebound tenderness followed pressing in the left lower quadrant. Rectal examination was negative. The reflexes were physiologic.

Laboratory studies showed a white-cell count of 10,500 with 79 per cent polymorphonuclear leukocytes. Examination of the urine was negative. A flat plate of the abdomen was negative for localizing signs and for kidney stones.

A diagnosis of acute appendicitis was made. Under spinal anesthesia, a right pararectus incision was made. When the abdomen was opened, some cloudy fluid was present, and the appendix was found to be greatly swollen and stiff, with one gangrenous area. The base was edematous and porky in consistence. The appendix was excised at its base, the stump buried, and the abdomen closed in layers without drainage. At this time, there was no suspicion that cancer was present.

Pathological examination showed an appendix measuring 6 cm. in length and 1.5 cm. in diameter. The surface varied from red to pink and showed occasional patches of yellowish fibrin. The wall was moderately distended, and at a point 2 cm. from the tip, there was a constricted area. The lumen was found with difficulty, especially in the proximal portion. The wall was markedly thickened, the cut surface being glistening and white. The distal half of the appendix showed a fairly definite lumen filled

with grayish fluid and a few smooth, hard, black masses measuring up to 0.3 cm. in diameter. When the larger masses were cracked, they were found to contain seeds.

Microscopically, three sections showed infiltration of the wall by small islands of cells, which frequently occurred as signet cells and were surrounded in part by bluish-staining mucoid material. In two sections, a rather broad area in the mucosa, although not extending entirely through the surface, presented an increase in connective tissue through which were scattered individual signet cells and small cords of cells. An occasional luminated structure was found, and frequent mitoses were present. In addition, the mucosa showed patches of necrosis, and the lumen contained polymorphonuclear leukocytes in several sections. On the outer surface, there was a mass of fibrinopurulent exudate, and, in one region, large numbers of bacteria, occurring as an abscess in the periappendiceal fat tissue. Figure 1 shows the histologic picture of the

FIGURE 1. High-Power View of a Section of the Tumor.

tumor. Diagnosis: primary carcinoma of the appendix, occurring chiefly as the colloid type, and acute appendicitis, with abscess formation and masses of bacteria on the serosal surface.

Three weeks later, an ileotransverse colostomy was performed. The germinal ileum for a distance of 60 cm. was found adherent to the cecum. In addition, there was a Meckel's diverticulum 45 cm. from the cecum. The patient made an uneventful recovery from this operation, and 10 days later, a right colectomy was done, the terminal 45 cm. of ileum, the cecum, ascending colon and hepatic flexure being removed. Histologic examination showed a few small islands of colloid carcinoma in the outer portion of the muscularis at the site of the appendiceal stump, but none elsewhere; the regional lymph nodes showed chronic inflammation but no evidence of tumor.

At a follow-up examination more than two years following the last operation, the patient stated that he had been symptom free and had been doing hard physical labor; neither x-ray nor physical examination revealed evidence of recurrence.

SUMMARY AND CONCLUSIONS

The literature for the past ten years is reviewed, true carcinoma confined to the appendix being found to be quite rare.

A case of acute appendicitis complicated by colloid carcinoma is reported

Colloid carcinoma of the appendix may cause no specific symptoms or signs, and since carcinoma may be indistinguishable grossly from acute inflammation, microscopic examination of all appendices removed at operation should be done

MEDICAL PROGRESS

THE BILE PIGMENTS (concluded)[†]

CECIL JAMES WATSON, MD[†]

MINNEAPOLIS

Recent clinical advances In 1936, a further modification of Terwen's method for the quantitative determination of urobilinogen in urine and feces was described.⁷¹ It was shown that the color intensities of mesobilirubinogen aldehyde and stercobilinogen aldehyde, as developed with Ehrlich's reagent in this method, were identical. More recently, this has been confirmed by means of the Evelyn photoelectric colorimeter, and the method has been applied to it,⁷² with excellent results.

Studies of jaundice, with particular reference to the daily excretion of urobilinogen in the feces and urine,⁷²⁻⁷⁵ have shown that helpful fundamental and diagnostic information may often be gained. With a modification of Rich's⁷⁴ classification of jaundice, as given below, the various forms noted are characterized in the main by urobilinogen excretion as indicated. The normal range was found to be 40 to 280 mg per day for the FU (feces urobilinogen)—usually 100 to 200 mg—and 0 to 35 mg per day for the UU (urine urobilinogen)—most frequently 0.5 to 1.5 mg. The value for the feces is an average for a four day period, whereas that for the urine is for 24 hours.⁷¹⁻⁷³⁻⁷⁵

I Retention jaundice may be defined as hepatocellular inability to remove bilirubin from the circulating blood, with resultant accumulation. There is an indirect or delayed van den Bergh reaction and no bilirubinuria.

A Hemolytic jaundice may be spheroidocytic or macrocytic, and the former may be familial or acquired in type. The FU ranges from 300 to 4000 mg per day, usually 600 to 2000 mg, and the UU varies from 10 to 200 mg per day, usually 50 to 300 mg.

The feces urobilinogen is commonly higher in patients with marked anemia or with hemolytic crises, but there is not a strict correlation.⁷⁶ Cases are seen with high values but relatively little anemia.⁷⁰ Contrary to frequently expressed belief, cases are often encountered with a marked increase in feces urobilinogen, but with a normal amount in the urine.⁷⁰ Such patients may have marked anemia, but relatively little, or even no, jaundice.¹⁻⁷⁰ In general, it may be stated that the more anemia, the less jaundice and urobilinogenuria and vice versa. The immediate period of hemolytic crises constitutes an exception to this, however.

B Constitutional hepatic dysfunction consists in constitutional hepatocellular inferiority in bilirubin excretion into the bile. This condition may or may not be familial. It has been described under various names and by different investigators,¹⁻⁷⁻⁷⁰ more recently by Dameshek,⁸⁰ under the designation of "familial nonhemolytic jaundice." The abnormality is characterized by simple accumulation of bilirubin, there is neither splenomegaly, spheroidocytosis or reticulocytosis nor any evidence of hepatic functional impairment other than faulty excretion of bilirubin.

The FU ranges from 100 to 200 mg, and the UU from 0.5 to 3.5 mg per day.

C Various factors, such as chronic passive congestion (often with pulmonary infarcts),

Reprints of articles in this series are not available for distribution but the articles will be published in book form. The current volume is *Med. Adv. Progr. in Ann. Vol. III 1942* (Springfield, Ill.) no. 3 Charles C. Thomas Company 1942 \$5.00.

[†]From the Division of Internal Medicine, University of Minnesota Hospital.

[†]Professor of Medicine, University of Minnesota, Chief of Medical Service, University of Minnesota Hospital.

[†]Watson C. J. Unpublished data.

pneumonia, virus and other infections, and poisons like arsphenamine and sulfanilamide, may produce a *mild retention jaundice*. This may become more marked, with developing evidence of regurgitation jaundice, or it may recede without this. Pure retention jaundice may be noted in the convalescent or later stages of any type of hepatitis. Not infrequently, especially with jaundice due to heart failure or pneumonia, a mild hemolytic component is present, as reflected in an elevated feces urobilinogen. The urine urobilinogen is nearly always elevated.

The F.U. varies from 100 to 500 mg. per day, usually 200 to 300 mg., and the U.U. from 5 to 100 mg. per day, usually 10 to 30 mg.

II. *Regurgitation jaundice* is caused by leakage or regurgitation of bile into the blood. Depending on the factors given below, this is due either to increased intrabiliary pressure with actual "rhesis" of the bile capillaries (especially ampullas) or smaller ducts,⁸¹ or to damage of these structures, resulting in increased permeability.^{82, 83} In either event, the bile probably gains access first to the lymph spaces of Desse, thence to the thoracic duct and the blood.^{81, 82, 84} The van den Bergh reaction is prompt or biphasic and bilirubinuria is present.

A. The *mechanical type* is caused by regurgitation of bile due to increased intrabiliary pressure.

1. *Cancer of the biliary tract* includes carcinoma, either primary or metastatic, and tumors of the lymphoblastoma group. The term "biliary tract" refers to the main hepatic ducts, the common hepatic duct, the common bile duct or the ampulla of Vater. Cancer involving these structures may be primary or secondary. A smooth, nontender, distended gall bladder is often palpable. There is complete biliary obstruction in about 90 per cent of cases.

The F.U. is less than 5 mg., and the U.U. less than 0.5 mg. per day.

Incomplete biliary obstruction is encountered in less than 10 per cent of cases.⁸⁵ This group includes polypoid and necrotic tumors and minute ampullary or common-duct carcinomas.^{73, 75} It may be emphasized that the depth of jaundice is not determined solely by the degree of biliary obstruction. Decreased bilirubin formation, or "throttling" of blood destruction following blood loss, results in a decrease of jaundice even though the biliary obstruction may remain complete.^{85, 86}

2. With *calculi*, the jaundice is usually fluctuant or intermittent. Colic and chills are com-

monly noted. Incomplete biliary obstruction is present in approximately 90 per cent of cases.⁸⁵

The F.U. ranges from 7.0 to 600 mg., and the U.U. from 0 to 50 mg. per day. This variation depends on several factors. With rapidly diminishing jaundice after spontaneous release of the obstruction, large amounts may be encountered for a short period. With low-grade obstruction, the amount may be within the normal range, although in some cases of this type it may be markedly decreased, probably because of a diminished rate of blood destruction. An impacted stone might be expected in a case with complete biliary obstruction. In my experience, this has usually not been found. Several cases have been observed in which the stone or stones were entirely loose in the duct and in which the reason for the complete obstruction was not apparent⁸⁵; conversely, impacted stones have been noted in several cases with incomplete obstruction.⁷³

The amount of urobilinogen in the urine depends on several factors, among which may be mentioned: the duration of the biliary obstruction and whether biliary or obstructive cirrhosis has developed; the presence or absence of cholangitis; and the degree of obstruction. Small amounts of urinary urobilinogen indicate hepatic functional impairment if but small amounts are present in the feces. This is probably true in jaundice of whatever cause.⁷³

3. In the majority of cases of *postoperative or benign stricture*, the obstruction is incomplete, but it appears that complete obstruction is encountered more frequently than with a common-duct stone.⁸⁵

The F.U. ranges from 0 to 300 mg., and the U.U. from 0 to 50 mg. per day. This variation of urobilinogen depends on the factors discussed in the foregoing paragraph.

4. *Chronic pancreatitis* causes jaundice but rarely; data on urobilinogen excretion are available from only 2 cases.⁸⁵ In one of these, the icterus was mild, and the biliary obstruction was not high grade; in the other, the clinical picture was that of carcinoma of the head of the pancreas, with the exception that the feces contained 9 to 22 mg. of urobilinogen per day during two four-day collections. The amount in the urine was negligible. This patient presented an easily palpable, nontender, distended gall bladder. At operation, the surgeon thought he was dealing with a carcinoma of the pancreas and performed a cholecystgastrostomy. The patient died of a postoperative hemorrhage (vitamin K at that time had not become available). Histologic

study of the pancreas obtained at autopsy first clarified the diagnosis, revealing a diffuse chronic fibrous pancreatitis.

B. The *parenchymal type* is any regurgitation jaundice due to diffuse liver damage (not secondary to mechanical obstruction). Acute and chronic hepatitis, damage due to toxins and chemicals, cirrhosis, diffuse carcinomatosis, and chronic passive congestion are included. Regurgitation of the bile is mainly the result of increased permeability of the bile capillaries (ampullas and small bile ducts and, at least in some cases, of intrahepatic bile-duct or bile-capillary obstruction, because of swelling of the liver cords, edema of the spaces of Disse³⁶ or fibrosis in the portal areas of the liver lobules.

The F.U. varies from 0 to 1000 mg. per day, usually 10-300 mg., and the U.U. from 0 to 300 mg., usually 0.5 to 100 mg. Of 57 cases of various types of parenchymal jaundice, only 2 (3.5 per cent) exhibited less than 5 mg. of fecal urobilinogen per day. Six were found to have less than 1 mg., and 4 less than 0.3 mg. in the twenty-four-hour urines.⁸⁵ These values may be compared with those given above for biliary-tract cancer and the calculous group.

1. *Hepatitis* may be divided into the groups shown in Table 1, with their corresponding

TABLE 1. *Types of Hepatitis with Particular Reference to Urobilinogen Excretion.*

Type	UROBILINOGEN EXCRETION	
	F U mg./day	U U. mg./day
Acute		
Early period (2 to 4 days)	10-100	10-100
Peak of jaundice (4 to 8 days)	0-20	0-10
Diminishing jaundice (7 to 30 days)	50-600	10-300
Subacute (1 to 2 months)	10-1200	0.5-300
Subchronic (2 to 6 months)	10-1200	0.5-300
Chronic (cirrhosis)		
With marked jaundice	10-1200	0.5-300
With mild or no jaundice	50-300	0.5-30

ranges of urobilinogen excretion. It is seen that, in some cases of acute hepatitis, urobilinogen is absent from the urine and feces during the peak of the jaundice. Insufficient data are available regarding the actual percentage of cases with complete exclusion of bile from the intestines during the height of the disease. The majority of cases that have been studied were first seen when the jaundice had already been present for some time and was beginning to diminish. From the available evidence, there is little doubt that a temporary, complete exclusion is not uncommon. Judged by simple inspection or by quali-

tative tests alone, however, complete exclusion has undoubtedly been believed to be commoner than it is. Grossly acholic feces may contain from 10 to 15 mg. of urobilinogen per day; correspondingly, a twenty-four-hour-urine sample may exhibit a negative qualitative Ehrlich reaction, and yet by the quantitative method^{73, 75} as much as 15 mg. per day may be detected. During the third or receding stage of acute hepatitis, urobilinogen usually reappears in the urine in large amounts. Serial qualitative tests are of much value at this point, since they often reveal the first evidence of beginning improvement—that is, the re-establishment of bile flow to the intestine. From this point on, the progress of convalescence may be followed by observation of the urobilinogen reaction each day. In a small percentage of cases of acute catarrhal jaundice, urobilinogenuria fails to appear during the convalescent period. It remains to be determined whether these are examples of catarrhal jaundice in the true sense of the word—a “catarrhal choledochitis”⁸⁷—or whether an actual hepatitis.

As noted above, a considerably increased fecal urobilinogen excretion may be observed as the jaundice diminishes in acute hepatitis and also, for longer periods and in greater degree, in the more prolonged cases, including some of those that progress to cirrhosis. There is every reason to believe that these increases are often associated with an increased rate of blood destruction. Outspoken hemolytic anemia may develop, with macrocytosis and increased reticulocytes.^{73, 76, 78} Splenic enlargement is usually marked. In van den Bergh and Kamerling's⁸⁸ fatal case of this type, there was a large amount of hematin in the circulating plasma. In passing, it might be noted that hematinemia has been emphasized repeatedly as an evidence of liver damage. Whether this is actually hematin or Fairley's⁸⁹ methemalbumin has not been determined.

2. *Toxins*, such as those occurring in pneumonia, peritonitis, hemolytic-streptococcus septicemia, gas-bacillus sepsis and other severe toxemias, may produce liver damage. F.U. ranges from 100 to 400 mg., and the U.U. from 10 to 200 mg. per day.

3. *Poisons*, such as arsphenamine, cinchophen, phosphorus, trinitrotoluene, sulfanilamide and many other substances, may result in liver damage. The F.U. varies from 10 to 1000 mg., and the U.U. from 0.5 to 300 mg. per day.

The jaundice seen following arsphenamine or cinchophen may be associated with almost complete suppression of bile flow—in some cases, quite complete. Arsphenamine jaundice may

simulate acute or subacute hepatitis, or so-called "catarrhal jaundice" quite closely. On the basis of clinical and histologic studies (liver biopsy) in 10 cases, Roholm and Krarup⁹⁰ have recently stated that arsphenamine simply lowers the resistance of the liver to the virus of epidemic hepatitis. Hanger and Gutman⁹¹ have described cases of arsphenamine jaundice similar to what Eppinger calls the "cholangiolitic type" of catarrhal jaundice in distinction to the ordinary, hepatocellular variety. Although there is no doubt of the existence of the two clinical types, there are many borderline cases, and so far as can be determined at present, there are no disturbances of pigment metabolism that are distinctive.

Cinchophen jaundice may likewise simulate acute hepatitis, especially in the appearance of the pigments. In a case previously recorded,⁷³ there was a history of recent ingestion of pills (probably cinchophen) for "rheumatism." Painless, deep jaundice, with anorexia and nausea, developed. At the height of the jaundice, the F.U. was 10.2 mg., and the U.U. 3.8 mg. When the jaundice had diminished, the former was 280 mg., and the latter 207 mg. This case illustrates well the high-grade but incomplete biliary obstruction, the importance of evaluating a relative increase of urobilinogen in the urine in favor of liver damage and, finally, the large amount in the urine during the re-establishment of bile flow, owing to residual disturbance of liver function.

Jaundice following sulfanilamide is rarely intense or associated with a very marked suppression of bile flow. There may be a prominent hemolytic factor, with outspoken anemia and increased fecal urobilinogen.⁹² Occasionally, cases are seen in which the jaundice deepens rapidly and death is due at least in part to severe hepatic injury, even acute atrophy. In my experience, however, jaundice of this degree has been observed only when there was reason to believe that the liver was damaged before the administration of sulfanilamide—for example, in the presence of severe infections or toxemias or when the drug was given to a patient also receiving arsphenamine treatment for syphilis.

4. Cirrhosis of the liver is of various types. In the foregoing discussion of "hepatitis," the chronic form was noted as being synonymous with cirrhosis. This does not indicate that all types of cirrhosis follow hepatitis. On the contrary, many are probably related to other factors, of which fatty liver, deficiency states (including chronic alcoholism) and various poisons, notably cinchophen and arsphenamine, may be emphasized. From the standpoint of the bile pigments, however, no fea-

tures differentiate the various etiologic factors. This is also true of hemochromatosis, although it may be noted that jaundice is usually not prominent in this disease.

5. In some cases of *diffuse carcinomatosis*, hepatic metastases are sufficiently extensive to impair liver function markedly. Considerable jaundice may be noted, even though the main hepatic ducts are uninvolved. Marked urobilinogenuria may occur,⁸⁵ and the clinical picture may closely simulate cirrhosis of the liver.

6. *Chronic passive congestion* has already been referred to as a cause of retention jaundice. In severe cases of so-called "cardiac jaundice," regurgitation jaundice is nearly always present as well.⁹³ Pulmonary infarcts are commonly found.⁹⁴ Urobilinogenuria is usually noted, and is often marked. Edelman and his co-workers⁹⁴ found an excess of urobilin in 88 per cent of their cases of heart failure. The presence of renal insufficiency or azotemia usually prevents or reduces urobilinogenuria.⁹⁵ Correspondingly, when crystalline stercobilin is administered intravenously in a patient with both hepatic and renal impairment, its elimination in the urine is markedly retarded.¹

Pulmonary or myocardial infarction is often productive of marked urobilinogenuria. Head* has shown that serial qualitative urine urobilinogen tests are helpful in the diagnosis and care of coronary thrombosis and its complications. There is considerable reason to believe that this indicates liver damage due to substances coming from the infarct. Urobilinogenuria occurring after a ruptured tubal pregnancy has been similarly explained.⁹⁶ After an attack of coronary thrombosis productive of an infarct, the urobilinogen reaction rarely becomes positive before the end of the first twenty-four hours and usually not before two or three days, quite in contrast with an acute biliary colic or acute cholecystitis, in which the reaction often appears almost at once. In the latter condition the urobilinogenuria is believed to be due to lymphatic drainage of bacteria or toxic material from the gall bladder into the liver, with resultant hepatitis or liver-function impairment.⁷³

The simple qualitative test for urobilinogen⁷¹ often yields valuable information, although it is true that in many cases nothing very decisive can be found without quantitative determination of the per-diem amounts in the feces and urine. Positive reactions in the feces usually indicate patency of the biliary tract, or at least that biliary obstruction

*Head, D. P. Unpublished data.

is not complete. Very weakly positive reactions are difficult to evaluate since they may be noted in the presence of complete biliary obstruction, such as that due to cancer. These reactions are probably explained by traces of urobilinogen derived from bile-stained epithelial cells or, in some cases, from bilirubin contained in the serum of blood that has entered the intestines from some source of hemorrhage in a patient with deep jaundice. One such case was seen recently in which it appeared probable that 11 mg. per day of fecal urobilinogen was on this basis. The amount of bilirubin provided by bile-stained mucosa probably never exceeds 5 mg. per day (in terms of urobilinogen), and yet this or smaller amounts may be sufficient to give weak Ehrlich reactions, which are likely to be confusing in diagnosis. If the qualitative test alone is to be used, one should rely only on a series of entirely negative or outspokenly positive reactions in attempting to assay the degree of biliary obstruction. Serial tests are also highly desirable for the urine.

In cases of liver damage, especially cirrhosis, the fluctuation in urobilinogen excretion from day to day, and even at different hours of the day, is often striking. Persistently negative reactions in patients with deep jaundice usually signify complete obstruction, although there are definite exceptions to this. Strongly positive reactions in patients with marked jaundice, but without any suggestion of cholangitis or biliary cirrhosis that might be secondary to a common-duct stone, are nearly always indicative of a parenchymal jaundice, due either to hepatitis or to cirrhosis. In a study of 80 cases of painless jaundice, White⁹⁷ found positive urinary urobilinogen reactions in 88 to 100 per cent, depending on the stage of the disease. This study was carried out with the Wallace and Diamond⁹⁸ method, which is simply a series of dilutions of the qualitative test. In a later paper, White and his associates⁹⁹ compared this method with those of Sparkman¹⁰⁰ and Watson.⁷¹ The former had been proposed as a simpler quantitative method. It employed single samples of urine or feces rather than daily collections. Various disadvantages and errors in this technic were subsequently noted by Watson and Bilde.⁷³ In the comparative study of White et al.,⁹⁹ the Sparkman method was found to have no advantage over that of Wallace and Diamond. Neither method was as accurate as the Watson⁷¹ modification of Terwen's¹⁰¹ procedure.

The qualitative test for urobilinogen may be masked by the presence of large amounts of bilirubin, especially when converted to biliverdin, as already mentioned. This is true, however, only

of small amounts of urobilinogen that under ordinary circumstances give but a weak (light-pink) reaction. In cases in which bilirubin or biliverdin might mask a weak reaction, the use of a spectroscope quickly determines the presence or absence of the characteristic urobilinogen-aldehyde band (maximum 565 millimicrons).

A number of substances exhibit yellow, red, or violet reactions with Ehrlich's reagent. These were discussed in detail by Naumann¹⁰² with particular reference to the question of false-positive tests for urobilinogen. In my opinion, these various substances have relatively little practical significance. The color due to indol or skatol disappears when the test is carried out in the proper way with sodium acetate.^{71, 101} I have not encountered false-positive tests due to other compounds with the exception of porphobilinogen,¹⁰³ a substance characteristic of acute porphyria^{103, 104} and readily distinguished from urobilinogen by virtue of chloroform insolubility after forming the Ehrlich compound.¹⁰⁴

Split Products of Hemoglobin or Bile Pigments

Pentdyopent. Prior to Bingold's studies,^{21, 105-108} it was customary to believe that the degradation of hemoglobin in nature went no farther than bilirubin and urobilinogen—in other words, that although the porphyrin ring in the hemoglobin molecule was opened, the four pyrrol nuclei remained intact in a chain. Although this is undoubtedly correct for a major fraction of the destroyed hemoglobin, at least under ordinary circumstances,¹ Bingold's work has clearly revealed that both hemoglobin and the bile pigments may be split in vitro to substances with but two, rather than four, pyrrol nuclei. This transition undoubtedly occurs in vivo to an extent that is probably variable under different conditions.

Bingold has shown that blood freed of its catalase by heating is readily decolorized by hydrogen peroxide. Subsequent reduction with sodium hydrosulfite ($\text{Na}_2\text{S}_2\text{O}_4$) is then productive of a pink color with an absorption band that, in potassium hydroxide solution, has an absorption maximum at 525 millimicrons. Bingold simply employed this maximum as a descriptive name: "pentdyopent." In ammonia, the maximum absorption is at 540 millimicrons. This reaction has been shown by Fischer and his co-workers^{109, 110} to be due to dipyrromethenes, which are undoubtedly formed during the above procedure by an oxidative splitting in half of the porphyrin ring in the hemoglobin or heme molecule. As excreted in the urine, the dipyrromethene giving the pentdyopent reaction on addition of sodium hydrosulfite is colorless; in other words, it

is excreted as a "propentdyopent." Bingold obtained considerable evidence that the kidney is responsible for the formation of this substance. He noted that in hemoglobinuria the hemoglobin was decolorized by peroxide without preliminary heating, whereas in hematuria heating was necessary, just as it is with human blood. This difference was assumed to be due to removal of catalase by the kidney. Native propentdyopent was observed in urines from many and various pathologic states, but not under normal circumstances. It was found most frequently in urines containing bilirubin, and since the latter has been shown to give the pentdyopent reaction itself, the possibility exists that the main source of the propentdyopent is bile pigment rather than a direct oxidation of the hemoglobin. Bingold states specifically, however, that the reaction has been observed when bilirubin was absent. It should also be noted that urobilin IX α is readily converted to pentdyopent, whereas stercobilin is not.¹⁰⁹ Thus, it is quite conceivable that any urine sample containing mesobilirubinogen may also contain propentdyopent, if one assumes that a part of the former substance has been oxidized in the kidney.

The clinical significance of the pentdyopent group remains to be determined. Preliminary studies intended to provide a quantitative procedure have shown only that this will be attended with numerous and perhaps insurmountable difficulties, owing principally to the instability of the color. There is little doubt that the substance deserves further study, especially regarding its importance to the whole problem of hemoglobin metabolism. The main question to be answered is whether any appreciable fraction of the destroyed hemoglobin is ever excreted as propentdyopent. From time to time, a perplexing situation is encountered in which ordinary studies of blood destruction fail to reveal the fate of considerable amounts of hemoglobin.

In a twenty-eight-year-old patient with Hodgkin's disease, fever and severe anemia, the hemoglobin was 5.65 gm. per 100 cc. During the next nine days, 2400 cc. of blood (equivalent to 260 gm. hemoglobin) was given in nine separate transfusions, at the end of which time, the hemoglobin was 5.75 gm. per 100 cc. The F.U. averaged 515 mg. per day total excretion (equivalent to 167 gm. hemoglobin), and the urine showed small amounts of bilirubin and urobilinogen; in addition, urine pentdyopent tests, performed every other day, were positive. The fecal urobilinogen in the above case clearly indicated a hemolytic process, but failed to account for approximately 100 gm. of transfused hemoglobin. Although the blood volume was not determined, it is unlikely that it could

have increased sufficiently to account for the discrepancy. In any event, the repeatedly positive pentdyopent reactions in such a case indicate the need for further study of this question.

Myobilin and mesobilifuscin. Until very recently, excretory products of muscle hemoglobin were unknown. Siedel and his co-workers^{111, 112} have therefore opened a new field of investigation in their descriptions of a dipyrromethene isolated from the feces in certain conditions. Meldolesi, Siedel and Möller¹¹² first reported the excretion of a substance designated as "myobilin" in the feces of patients with progressive muscular dystrophy. This pigment was characterized by a brown color and a spontaneous green fluorescence (without zinc). The latter disappeared as the pigment was purified, and it was subsequently shown that the fluorescence was related to a combination of the pigment with protein. The substance was not detected in the urine, and it was thought that this was because the chromoprotein molecule was too large. No mention was made of its presence in the bile or of how the molecule was excreted by the liver. Interestingly enough, large amounts of the pigment were found in the feces of women during the first week of the puerperium, in whom it was thought that the pigment was derived from the myohemoglobin of the involuting uterus; in the patients with muscle atrophy or dystrophy, it was ascribed to the loss of hemoglobin from the voluntary muscle. The marked increase of myobilin in the feces was correlated directly with the hemoglobin-poor muscle.

After removal of the protein from the myobilin molecule, the underlying pigment was found to be a dipyrromethene, which was identified with mesobilifuscin, a substance that is dark brown, and does not fluoresce either spontaneously or with zinc; the zinc compound is relatively insoluble. The pigment could not be crystallized. These characteristics are entirely similar to those of the substance described several years ago under the name of "copronigrin," a brownish-black pigment obtained from the feces and characterized by an insoluble zinc compound.⁵⁴ It was recognized later that an entirely similar material could be obtained by oxidation of urobilin or stercobilin.¹ This is also quite in accord with the finding of Siedel et al.¹¹² that mesobilifuscin is present in the oxidized amorphous material (the so-called "Körper II") remaining after the reduction of bilirubin to mesobilirubinogen.

It is obvious that these newer studies raise many questions regarding not only the relatively unexplored field of myohemoglobin metabolism but also the whole problem of the bile pigments.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 28451

PRESENTATION OF CASE

A forty-two-year-old housewife was admitted to the hospital because of high blood pressure and a cough productive of small amounts of blood.

Four years prior to admission the patient had a "dizzy spell." Because of an elevation of blood pressure and increased hair about the face her physician sent her to another Boston hospital for adrenal studies. On admission at that hospital her blood pressure was 225 systolic, 150 diastolic. Peri-adrenal air insufflation studies and bilateral adrenal explorations were made. The adrenals were said to have been normal, and no ovarian tumors were felt. Owing to wound sepsis complicating the postoperative course, the patient was hospitalized for more than a month. At the time of discharge her blood pressure was 160 systolic, 110 diastolic. She soon became active again and remained so until one year prior to admission. At this time, after working rather hard in the garden, she began to cough up a "bloody sputum." At this time she noticed some blurring of vision. After approximately two weeks, these symptoms subsided and she seemed well. Two or three months before entry she developed exertional dyspnea and vision was again impaired, and six weeks before she had another episode similar to that noted a year previously; cough productive of bloody sputum continued to the time of admission. During this last attack, dyspnea became progressively worse and at times she noted "attacks of feeling as if there was a weight on the chest." During the week prior to admission there was mild ankle edema. She had been taking 1 tablet of digitalis each day during the six months before entry to this hospital.

The family history was noncontributory. There were two uncomplicated pregnancies eighteen and twelve years before entry.

Physical examination revealed a fairly well-nourished woman sitting up in bed and obviously making no attempt to minimize her discomfort. The skin seemed exceedingly thin and atrophic. The facial hair was noticeable but not heavy. Respirations were rapid but apparently not labored. There was questionable cyanosis of the lips. The neck veins were moderately distended.

Both optic disks were blurred. There was a marked arteriovenous nicking, and there were several small flame-shaped areas of hemorrhage in the right fundus. The anteroposterior diameter of the chest was slightly increased. The left side seemed to lag a bit with inspiration. At the left base posteriorly there were dullness to percussion, absent tactile fremitus, decreased vocal fremitus and diminished breath sounds. These signs disappeared toward the axilla. Over the lower half of the right lung posteriorly there were a few coarse rales. The heart was moderately enlarged to percussion, and the sounds were of fairly good quality. No murmurs were audible. There was marked tenderness in the right upper quadrant. The liver edge could not definitely be felt, but dullness was percussed below the costal margin. There was moderate clubbing of the fingers—the patient indicated that her fingers had always had this shape and that her father's fingers had a similar shape. The examining physician added the note that on observing her raise the bloody material it did not seem to come from the lungs.

The blood pressure was 220 systolic, 140 diastolic. The temperature was 99.6°F., the pulse 90, and the respirations 25.

The examination of the blood revealed a red-cell count of 3,900,000, and white-cell count of 12,900 with 72 per cent polymorphonuclears. The hemoglobin was 60 per cent. The urine was alkaline in reaction, had a specific gravity of 1.010 and gave a +++ test for albumin; the sediment contained a rare red blood cell and a few white cells per high-power field. The blood Hinton test was negative. The blood nonprotein nitrogen was 40 mg. per 100 cc., and the serum protein 7.2 gm., with the albumin 2.2 gm. and the globulin 5.0 gm., making a 2.4 ratio. The van den Bergh test was normal. The prothrombin time was 30 seconds (normal, 25 seconds). The cephalin flocculation test was 0 at 24°C. and \pm at 48°C. The fasting blood sugar was 145 mg. per 100 cc. The 17-ketosteroids excretion in the urine was 2.4 mg. every twenty-four hours. A urine culture revealed nonhemolytic streptococci. An electrocardiogram demonstrated a normal sinus rhythm with a rate of 86. The PR interval was 0.16 second. There were left-axis deviation, depression of the ST segment in Leads 2 and 4, and a diphasic low T wave in Leads 1 and 2. Repeated studies of the basal metabolism revealed rates ranging from +31 to +56 per cent.

An x-ray film of the chest showed spotty hazy areas of increased density throughout the midlung fields, more marked on the right side. There was a small amount of fluid at the right base, and a larger amount at the left costophrenic angle. The

aorta was calcified but not dilated. The heart was enlarged, chiefly in the region of the left ventricle. An intravenous pyelogram showed normal kidney outlines and poor dye excretion.

The patient was treated with digitalis and Mercupurin without much improvement. On the fifth day after admission, in preparation for a phenosulfonephthalein test, 1000 cc. of water was administered by mouth. This resulted in early anuria and later in dysuria. The next day, one hour following the administration of an evening sedative (3 gr. of Amytal), she became irrational and restless. Cheyne-Stokes respirations developed a half hour later. A stomach lavage stopped the irregular respirations, but two hours later these recurred. Ten cc. of aminophyllin was administered intravenously and permanently stopped the Cheyne-Stokes respirations.

Two days later she complained of severe back pain, which radiated to the left. The urine had a specific gravity of 1.020 and gave a +++ test for albumin and a +++ test for diacetic acid, and the sediment contained 1 red cell and 1 white cell per high-power field. Catheterized specimens of urine examined on the succeeding days contained many red cells and occasional white cells. No casts were found. The blood chloride was 92.5 milliequiv., and the bicarbonate 26.0 milliequiv. per liter. At this time the temperature was slightly elevated, reaching an evening peak of 100°F., and she complained of generalized aches and pains. Another chest roentgenogram still showed the same findings. On the nineteenth day after admission the patient said she felt poorly and complained of some nausea. Three days later she suddenly collapsed and had generalized convulsions. These ceased in a few seconds. When seen by a physician she was cyanotic. The heart sounds were inaudible, but feeble gasping respirations were present. She died within three minutes of the observed onset of the attack.

DIFFERENTIAL DIAGNOSIS

DR. WYMAN RICHARDSON: I might interpolate here that one would be anxious to know whether these clubbed fingers showed a softening at the base of the nail, so that when you pressed them the nailbed seemed to be slightly afloat, because I do not believe you ever see that in congenitally clubbed fingers. I am going to disregard this finding.

The blood was slightly hypochromic, which probably is not significant.

I should like to see the chest plates.

DR. GEORGE W. HOLMES: The films cover a period of a little over a month. One film of the chest was taken in June, and the others in July. It

is obvious that there is a lesion in the chest. The process is at the base of the lung, more on the right than on the left. It is accompanied by a moderate enlargement of the heart, chiefly to the left in the region of the ventricle. This second film was taken with a Bucky diaphragm and overexposure to bring out the character of this process in the lower part of the chest. I think the bronchial shadows are enlarged. In other words, this looks like a bronchiectasis so far as the chest films go. I do not see any definite evidence of fluid. My interpretation may be wrong, but that is the first thing I should think of.

DR. RICHARDSON: How about congestion due to cardiac failure?

DR. HOLMES: I should not think so. In the first place, the heart does not have the shape seen in cardiac failure. There is some dilatation, but it does not look like a failing heart. The auricles are not dilated enough to account for the change in the lung fields.

DR. RICHARDSON: It is not the condition of localized edema associated with renal failure that we have been shown by Drs. Schatzki and Scott?*

DR. HOLMES: It does not look like it to me.

DR. RICHARDSON: I was caught on that before.

DR. HOLMES: There is such a thing; I cannot say that it is not present, but my impression is that it is not. In the films taken of the abdomen, the kidney outlines are quite evident on both sides and the right kidney is distinctly larger than the left but both of them, I think, are within normal limits. Such a slight difference in size would not mean anything definitely abnormal.

DR. RICHARDSON: Supposing you were thinking in terms of myeloma kidney, do you see anything suggestive there?

DR. HOLMES: I should expect them both to be enlarged in that case. The most likely interpretation of the kidneys is that the right was not functioning well and that the left kidney had undergone compensatory hypertrophy. The liver shadow is well seen, and this, I think, is the spleen. If it is spleen, there is no definite enlargement, nor do I think that the liver is enlarged.

DR. RICHARDSON: But you would not say that it was small?

DR. HOLMES: No. Of course, x-ray evidence of change in the size of the spleen is not accurate. But I certainly should not interpret that as being particularly abnormal.

So far as the excretion of the dye is concerned, it is very poor. If the test was carried out properly, I think we can interpret this as evidence of poor function in the kidney.

*Schatzki, R., and Scott, A. T. Unpublished data.

DR. RICHARDSON: How about the bone structure?

DR. HOLMES: It is well within normal limits; I do not see any decalcification or any other change.

DR. RICHARDSON: They did not do the skull?

DR. HOLMES: No.

DR. RICHARDSON: In the first place I am going to try to lay this endocrine ghost that has been stalking around through this whole story. It is not clear why they operated on the adrenal glands at the other hospital, whether to look for an adrenal medullary tumor, a so-called "pheochromocytoma," or whether to look for an adrenal cortex tumor. If you glance through the record for evidence of endocrine difficulty you find it but it all points in different directions. In the first place, she had two uncomplicated pregnancies. The menstrual history is not mentioned; with the history of normal pregnancy we probably can consider it normal. We are not sure whether she was amenorrheic at the time of entry. I think facial hair that is noticeable but not heavy is not to be overemphasized. It is a common hereditary characteristic. Thin and atrophic skin may suggest an overactive anterior pituitary gland. The laboratory finding of decreased 17-ketosteroid excretion is absolutely opposed to an adrenocortical tumor and in the opposite direction from the increased basal metabolic rate. I cannot see how one can talk about Cushing's syndrome in this case by any stretch of the imagination just because she has a little hair, hypertension and slight anemia. I cannot explain, incidentally, the lowered ketosteroid excretion by any theory. I do not know much about endocrine disease, but I will say that I doubt that Dr. Mallory will find any very striking primary disease involving the endocrine glands.

There are two ways of attacking this problem, one from a purely clinical angle and the other from the laboratory findings. If I take the clinical angle alone, I think this patient had hypertensive heart disease, cardiac failure and renal failure, probably secondary to renal congestion; and the manner of death, although rather sudden with convulsions, is best explained on the basis of cardiac failure or some vascular difficulty. If I look at the laboratory side of it, I am going to get into trouble. She had a mild anemia, possibly accountable on the basis of some renal failure and her general condition. Then there was this serum protein of 7.2 gm. per 100 cc., which is on the high side of normal, particularly since the normal values have recently been running about 6 gm. or a little over. At any rate, the globulin is markedly and definitely increased.

One cannot take too seriously any single laboratory finding, but I think one has to take this seriously. When I try to figure out what diseases produce increased globulin to this extent, there are not many that I have to mention. Certainly not cholera or lymphogranuloma inguinale; and I do not believe that sarcoid would kill the patient. I come down to two causes that seem likely—multiple myeloma and some disease of the liver like cirrhosis.

I get all balled up with electrocardiograms, but I do not see anything specific here. I shall ask Dr. Harwood to give an opinion, but before he says anything, I shall say that the tracing is consistent with hypertensive heart disease and failure.

DR. REED HARWOOD: I agree.

DR. RICHARDSON: Dr. Holmes bothers me by not being willing to say that the x-ray findings might be related to cardiac failure.

DR. HOLMES: I should not say that they could not be. On the other hand, I think they are less likely to be that than something else.

DR. RICHARDSON: Regarding the clubbed fingers, I remember a recent case in which they were very important in connection with bacterial endocarditis, but I cannot see that this case hooks up in any way with bacterial endocarditis. I considered the question of periarteritis nodosa or some similar vascular disease, but I do not see any point in talking about that without more definite evidence. You can have renal and vascular changes in periarteritis nodosa, but not necessarily hypertension and usually more fever. In this case the whole story does not seem to me to fit that sort of disease. So that I have come down rather reluctantly to two diagnoses. One is hypertensive heart disease, with some question in regard to what the kidneys might show,—probably congestion of the kidney with failure and rather fine vascular changes,—with perhaps some vascular changes in the brain, possibly small areas of hemorrhage, and with cirrhosis of the liver on some basis either entirely incidental or possibly the "rare bird" that I almost never see and talk too much about—cardiac cirrhosis. That is one possibility. The only other thing I can do is to say that this patient had a plasma-cell myeloma with myeloma nephrosis, renal failure, hypertension on this basis and the train of symptoms following hypertension with combined renal and cardiac failure. I have not seen many of these cases, but to me they showed renal failure much more clearly than this patient showed. The only things in favor of it are the high globulin, the poor renal excretion of dye and the albuminuria. Bence-Jones protein was not looked for. Since I put myself on the horns

of that dilemma, the obvious thing to do is to take the common disease, and I am going to say that this patient's difficulty was routine hypertension resulting in cardiac failure and mild renal failure, largely on a congestive basis, with vascular changes in the kidneys and cirrhosis of the liver (? "cardiac").

DR. TRACY B. MALLORY: I should like to ask Dr. Holmes if in the last film he can see anything in the superior mediastinum.

DR. HOLMES: I can see something in the last film that is not in the first. It is beneath the clavic on the right side. It did not impress me.

DR. MALLORY: You do not care to go farther?

DR. HOLMES: Recently we have seen a series of cases with shadows of that kind, which turned out to be due to the innominate artery. Most of them are normal. They are usually caused by tortuosity of the aorta. Aneurysm of the innominate artery, however, can produce such a shadow, as can a large peritracheal lymph node.

CLINICAL DIAGNOSES

Hypertension.

Hypertensive and coronary heart disease.

Coronary occlusion.

DR. RICHARDSON'S DIAGNOSES

Hypertension.

Hypertensive heart disease.

Congestive failure.

Vascular nephritis (slight).

Cirrhosis of the liver (? "cardiac").

ANATOMICAL DIAGNOSES

Dissecting aneurysm of aorta, with rupture into mediastinum and left pleural cavity.

Hematoma, left.

Hypertrophy of heart, hypertensive type.

Arteriosclerosis, marked: aorta.

Pyelonephritis, chronic, inactive.

Cystitis, acute.

PATHOLOGICAL DISCUSSION

DR. MALLORY: When this patient first came in, she obviously impressed everyone who saw her as the complaining sort. Consequently from then on when she had discomfort they discounted it heavily. She did complain bitterly of pain in the back, and the note in the record reads, "Patient complains of pain in the back, probably postural." Nothing was done about it. In another note, it is stated that she complained of aches and pains all over but apparently no specific inquiries were made as to where they might or might not be. That is unfortunate because she unquestionably did have severe pain in the back, owing to a dis-

secting aneurysm. The dissection had evidently occurred some time before death. The day on which she complained of severe back pain was fourteen days before death, and the blood in the outer channel was not merely clotted but partially organized. It was also evident that at the time of or immediately following the initial attack of dissection the outer wall had torn slightly; this resulted in a leakage of blood into the superior mediastinum, where a hematoma of considerable dimensions was present, which likewise showed organization. This must have been present at the time the last chest film was taken.

The terminal episode in this patient was a further rupture of the outer layer into the mediastinum and hence into the left pleural cavity, which contained 2500 cc. of fresh blood.

The kidneys were interesting. They were somewhat small, weighing 250 gm., but markedly scarred, and both showed an extremely severe vascular disease with disproportionate destruction of the tubules as compared with that of the glomeruli. Whether it was entirely a vascular nephritis or whether there was an underlying old pyelonephritis, I am not certain. I am tempted to believe this was hypertension based on a long-standing and inactive pyelonephritis.

The terminal changes in the urine,—the occurrence of numbers of red cells and so forth,—I think was not due to any interference with their blood supply by the dissecting aneurysm but rather to the development of acute hemorrhagic cystitis, which was merely a terminal complication.

The liver showed a very mild chronic type of congestion and by no stretch of the imagination could you call it "cardiac cirrhosis." The bone marrow showed no plasma cells. The lungs showed a little emphysema and fibrosis, so the pulmonary changes were not entirely due to congestive failure. We did not find any clearly defined bronchiectatic cavities, however, so I am left with absolutely no explanation of the elevated globulin and reversed albumin-globulin ratio. We found no evidence of endocrinopathy; the pituitary, thyroid and adrenal glands and the ovaries were all quite normal.

CASE 28452

PRESENTATION OF CASE

First admission. A fifty-eight-year-old physician was admitted because of diarrhea and pain in the right lower quadrant.

For fifteen years prior to admission the patient stated that he tended to have frequent episodes of diarrhea approximately every two or three weeks, each lasting two or three days. These

were usually accompanied by gaseous eructations and sometimes by a spell of vomiting. Occasionally there was a coincident fever. Hypogastric cramps occasionally accompanied the diarrhea, and often these were localized in the right lower quadrant. There was some mucus in the stools, but they were never tarry and did not contain blood.

In addition to the fairly mild episodes in which he had three or four loose movements each day, he had two acute attacks, one six years and another eight weeks before entry, in which he was prostrated by acute abdominal cramps, nausea, vomiting, very frequent watery stools, fever and an initial chill. The most recent episode began about twenty hours before admission when, following a hearty dinner, he began to have watery stools, vomited, retched several times and had generalized abdominal cramps. There was apparently no fever. He had a miserable night but felt better the next morning. During the next day he had two formed stools but later in the afternoon he had a shaking chill. His physician reported that his temperature was 103°F. There was no further diarrhea. The patient believed that oranges or pineapple juice, onions, and fresh fruits in general upset him and initiated the diarrhea. There was no weight loss.

The family history was noncontributory.

The patient had had a severe attack of scarlet fever at the age of fourteen, followed by nephritis, which later went into a nephrotic stage with persistent albuminuria for more than twenty years. He believed that he had had no albuminuria during the subsequent twenty-two years. He had taken several trips to the West Indies within the previous ten years, and on one occasion had had an attack of diarrhea that lasted only one night. Four years before entry, he had an attack of severe substernal pain after walking four blocks. This lasted five minutes and never recurred. Eight weeks previously, during the attack of diarrhea, his heart rate jumped to 180 but returned to a normal rate after pressure was applied to the carotid sinus. He had been taking some alkali in recent months for gaseous eructations and "heart burn."

Physical examination revealed a slightly flushed, obese man in some discomfort. The examination of the heart and lungs was negative except for scattered fine moist rales audible over the posterior bases of both lungs. The abdomen was soft and protuberant. There was no rigidity, and no masses were felt. There was a slight amount of tenderness over most of the right lower quadrant. No costovertebral tenderness could be elicited. The peristaltic sounds were hyperactive.

No tenderness was found on rectal examination, and the prostate was not enlarged.

The blood pressure was 142 systolic, 82 diastolic. The temperature was 98°F., the pulse 110, and the respirations 20.

The examination of the blood revealed a hemoglobin of 14.7 gm. and a white-cell count of 14,100 with 92 per cent polymorphonuclears, 6 per cent lymphocytes and 2 per cent monocytes. Twenty-four hours later the white-cell count had dropped to 11,400 with 71 per cent polymorphonuclears. Further white-cell counts showed figures consistently less than this. A blood Hinton test was negative, as was the urine examination. The blood nonprotein nitrogen was 22 mg. per 100 cc. The stool was greenish brown and guaiac negative; no amebas or amebic cysts were seen. An electrocardiogram demonstrated a normal sinus rhythm of 100 and slightly lowered T waves.

A flat plate of the abdomen showed what was interpreted as tuberculous lymph nodes in the right lower quadrant. There were no abnormal gas or soft-tissue shadows. The kidney outlines were normal. There were no shadows present that could be interpreted as stones. A barium enema showed that the colon filled readily; there were no constant irregularities or filling defects. About 15 cm. of the terminal ileum filled, and there was a constriction in its terminal portion opposite the tip of the cecum. The appendix was not visible. Practically all the barium was evacuated. Later a barium meal revealed a small hiatus hernia and fairly persistent spasm of the antrum of the stomach and the pyloric valve. The stomach and duodenum were otherwise normal. Serial examinations of the small bowel revealed no evidence of obstruction, but the constriction in the terminal ileum was again demonstrated. The mucosa at the site of the constriction was distorted and appeared to have been destroyed over an area less than 1.0 cm. in length. The cecum did not remain filled completely, there being a gap between the terminal ileum and transverse colon producing the so-called "Stierlin sign." The mucosa of the cecum and ileum appeared normal. The appendix did not fill. There was no dilatation of the small bowel.

The stools were repeatedly examined for the presence of amebas and amebic cysts, employing the zinc sulfate flotation method, but without success.

After nine days of hospitalization the patient was discharged without an established diagnosis. He was told to return after a month of rest for an exploratory abdominal operation.

Second admission (one month later). Following discharge the patient had felt well. During

the interval he had not suffered with tenesmus, cramps or diarrhea.

There was no definite change in the physical examination, and on the second day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. CLIFFORD FRANSEEN: This case, in summary, resolves itself into the differential diagnosis of lesions of the terminal ileum that are chronic and produce partial intestinal obstruction or perhaps chronic or recurring intussusception in a man of fifty-eight. Except for the findings in the right lower quadrant, the data do not seem to be relevant. The history, of course, is important, especially the fifteen-year duration, if one is going to try to make a single diagnosis that will explain the symptoms over all these years. Throughout this period he had recurrent inflammatory episodes and obstruction, cramps, nausea, vomiting, watery stools and so forth. One must depend on the x-ray findings in the right lower quadrant because he had no palpable mass.

The diagnoses to be considered are several. The first thing that suggests itself from the x-ray findings is tuberculous nodes in the right lower quadrant. Presumably the record means that calcified nodes were found. These can occur coincidentally in a large number of people of this age in x-ray examinations for other conditions, and alone they do not establish the diagnosis. Similarly, the appendix did not fill. In a large percentage of patients of this age who have routine examinations, I am quite sure the appendix does not fill, and it may not be important in this case.

I wonder if we may see the x-rays before we go any farther.

DR. RICHARD SCHATZKI: This is the barium enema, and this represents the small area of narrowing that is described in the record. It is about 1.5 to 2.0 cm. in length and is constant because the film taken after evacuation also shows it. I should agree with the record that the mucosal pattern is markedly distorted and that the mucosa seems to be destroyed. This is another set of films taken after the oral administration of barium, and you can see this same area again. It is certainly a well-localized destruction of the ileum.

DR. FRANSEEN: Would you care to say a word about Stierlin's sign?

DR. SCHATZKI: I think what the examiner meant is what a Swiss roentgenologist described thirty years ago—namely, a constant failure of the cecum and of the adjacent part of the ascending colon to fill during barium examination by mouth, in association with tuberculosis of the ileocecal re-

gion. I should say this was suspicious of it but by no means definite.

DR. FRANSEEN: This could be present in any condition that gives spasm of the cecum?

DR. SCHATZKI: Very definitely so. The record does not say anything about the cecum, but it appears normal so far as I can see.

DR. FRANSEEN: Is that area at the lower end of the cecum significant? It does not show the same smooth outline as the rest.

DR. SCHATZKI: It looks quite normal on the postevacuation film, however.

DR. FRANSEEN: To go back to the things we have to consider. First, we have tuberculosis. Are these the calcified areas here?

DR. SCHATZKI: Yes.

DR. FRANSEEN: They are calcified retroperitoneal nodes. If one considers a tuberculous process that has gone on over a period of fifteen years, it seems to me that one would expect to find more than is seen here. This lesion appears primarily to involve the ileum, over a relatively short segment, and not the cecum. After fifteen years one would have expected an inactive process, probably a cicatrizing lesion, which might simulate this condition.

I am trying to recall an interesting case in a man somewhere around fifty years of age that we had three or four years ago. The only lesion he had was a minute constricting area some distance from the ileocecal valve. If I had not known of that case I should not be suspicious of this area as being due to tuberculosis. It is my impression that tuberculosis is primarily an ulcerating process and would occur most likely in a younger man.

The next thing to consider, of course, is regional enteritis. It, too, is a disease of youth. I personally do not remember any case in a patient as old as this man, nor do several of my colleagues whom I questioned. Regional enteritis usually occurs in patients under forty. It is primarily a disease of youth, and probably of not so long duration as this condition, which has gone on for fifteen years. It also seems likely that if it had gone on to this stage of intestinal obstruction a mass would have been found, which is not true. Furthermore, the typical x-ray appearance of the bowel with the usual string sign is not present. The last patient I saw who had the string sign was a man of forty who proved to have an adenocarcinoma, so that sign may also be misleading. I should not consider regional enteritis seriously for these reasons.

Other inflammatory processes must be discussed because there were recurrent episodes. An appendix abscess sometimes produces bizarre findings, but under this diagnosis one would have to

make some other explanation for the episodes preceding the present one unless the patient had an obscure chronic appendicitis associated with obstruction. Also, no mass was palpable, so that there is not much reason to consider appendix abscess in this case.

One must, of course, consider a tumor. The malignant tumors that perhaps most frequently involve this segment of the bowel are sarcomas of the small intestine, carcinomas and lymphosarcomas. Lymphosarcoma would probably involve a larger area. The long duration is against malignancy unless it had been superimposed on a benign condition over these years. One might consider that the repeated episodes of obstruction were caused by intermittent intussusception or partial intestinal obstruction by some benign tumor in this region, but the usual benign tumors, such as lipomas, xanthomas and fibromas, are ordinarily somewhat pedunculated and are not circular and constricting as this lesion appears to be. The only other condition that I can consider in which one could have a benign tumor which would gradually advance and produce this picture is a carcinoid. The small intestine is the commonest site of carcinoid, except the appendix. In this case, one might suppose that the appendix was the primary site of the carcinoid and that the area in the ileum was involved secondarily, but I think that a primary carcinoid of the ileum is more probable. That would fit in best with the history of fifteen years' duration, because these tumors grow very slowly; however, I do not know of any case of carcinoid with such a long duration. It is conceivable that it might occur because other similar benign conditions can go on and produce symptoms like these until the final episode of more complete obstruction. The patient was in the age group in which carcinoid commonly occurs—another point in its favor. Likewise, the mass was small. Carcinoids can, of course, grow to considerable size and metastasize.

I should have to use carcinoid of the ileum as the diagnosis best fitted to this case. Tuberculosis cannot be entirely excluded, but I think it is unlikely.

DR. SCHATZKI: If our impression is correct that the mucosa was destroyed, does that not argue against the diagnosis of carcinoid?

DR. FRANSEEN: Yes; but that is at variance with the opinion given in the abstract. It says that the area was possibly destroyed over an area 1 cm. in length, which would be consistent with carcinoid. Of course, if the carcinoid had become malignant, the destruction of the mucosa would be consistent.

DR. SCHATZKI: I do not know the answer, but I should say from looking at the films that the mucosa was destroyed.

DR. FRANSEEN: That would be very much more in favor of a malignant process, possibly carcinoma.

DR. MALLORY: Even in cases in which carcinoids have become invasive and have metastasized to the regional lymph nodes we have not seen even one case with ulceration in the mucosa. It grows in a disk-like form in the submucosa and never spreads through to the surface.

DR. FRANSEEN: But when carcinoma intervenes, what occurs?

DR. MALLORY: That does not happen. A carcinoid is not an epithelial tumor and never turns into carcinoma. It is potentially a malignant tumor in its own right but does not become a carcinoma: it remains an argentaffine tumor.

DR. FRANSEEN: I understand that is a disputed point among pathologists. You believe that it does not become carcinomatous?

DR. MALLORY: Yes; Masson showed very definitely that it is a tumor of some peculiar nerve end organ rather than a tumor of the epithelium.

CLINICAL DIAGNOSIS

Regional enteritis?

Tuberculosis?

Appendix abscess?

DR. FRANSEEN'S DIAGNOSIS

Carcinoid of ileum, probably malignant.

ANATOMICAL DIAGNOSES

Appendicitis, healing.

Inflammation of Meckel's diverticulum, acute.

PATHOLOGICAL DISCUSSION

DR. MALLORY: I am sorry Dr. Arthur W. Allen, who operated on this patient, is not here to discuss the case. On the first entry, the patient was studied by Dr. Allen and Dr. Chester M. Jones and was discharged with three questionable diagnoses: regional enteritis, tuberculosis and appendix abscess. It was eventually decided that the possibility of appendix abscess was great enough so that he should return for operation as soon as he could adjust his affairs, and that was done.

On the second entry he was promptly operated on, and the first thing that popped into sight when the abdomen was opened was a Meckel's diverticulum. A little further exploration showed an appendix buried in adhesions along the brim of the pelvis, with no pus about it and no evidence of abscess. Both the appendix and the Meckel's diverticulum were removed. The surgeon's impression was that the appendix had been recently inflamed and was in a subsiding stage. In the laboratory, we formed another impression.

The appendix did not impress us greatly, and the Meckel's diverticulum contained purulent exudate in the lumen. So we believed there was an acute or still active diverticulitis and that the appendix, which was about two thirds obliterated, had undoubtedly, at various times in the past, been the seat of an inflammatory process but probably not in an extremely recent period. The anatomic findings are difficult to correlate with the x-ray findings, and yet I think we must assume that Dr. Allen was able to rule out such possibilities as tuberculosis, regional ileitis and carcinoid since he had a good exposure of the entire terminal ileum and nothing was found except the Meckel's diverticulum.

DR. SCHATZKI: How far away from the ileocecal valve was the Meckel's diverticulum?

DR. MALLORY: I judge very close, but it was not measured.

DR. SCHATZKI: This lesion is only 5 cm. proximal to the ileocecal valve. That would be very low for a Meckel's diverticulum. Furthermore, I still cannot see a diverticulum.

DR. GLENDY: How often can you demonstrate it?

DR. SCHATZKI: We hardly ever see the diverticulum itself, probably because it looks so much like the intestine. This is particularly true in the usual position of a diverticulum, higher up where it is difficult to distinguish the intestinal loops. But in this case the questionable loop is clearly separated. The diverticulum should have shown up, unless its entrance was closed and therefore did not fill with barium.

DR. MALLORY: The operative note said that the walls about the mouth were very thick.

DR. SCHATZKI: Then that is a possibility; however, the position is unusually low for a Meckel's diverticulum.

DR. GLENDY: Do you think that the diverticulum was close enough to the area of narrowing to produce spasm?

DR. MALLORY: That is my hypothesis. I think anyone has a right to disagree with it. I do not believe we have proved it at all.

DR. FRANSEEN: Spasm could not produce destruction of the mucosa.

DR. SCHATZKI: Obviously, the mucosa was not destroyed, just swollen.

* * *

The following post-conference statement was obtained from Dr. Arthur W. Allen:

I regret having been absent from the clinicopathological conference on Case 28452, because I could have cleared up many of the points that seemed to worry the discussers.

In the first place the patient gave a very atypical story for appendicitis, since in addition to nausea, vomiting and abdominal pain he had profuse diarrhea. This is very unusual in appendicitis because the inflamed appendix usually does not rest near enough to the rectum to produce peristalsis by irritation.

The patient entered the hospital twenty hours after the onset of his episode, and although he had a leukocytosis consistent with an inflammatory process, the abdomen was generally tender and there was no evidence of localization, either abdominally or by rectal examination. Finally, however, he did develop tenderness in the right lower quadrant.

The probability that the condition was due to appendicitis was so strongly considered that the patient was strictly Ochsnerized, and he made a fairly prompt response to this treatment. His temperature, having reached 103°F as a peak, came down to normal on the fourth day. Peristalsis, which had ceased after he entered the hospital, again became normal, and food and fluids were resumed by mouth.

The repeated minor episodes, with two previous severe attacks, always associated with a very sensitive colon, made us wonder whether the whole process might be accounted for on some basis other than simple, acute appendicitis. Very careful studies were made, including many stool examinations for amebae, since his first severe episode had taken place while on a Caribbean cruise.

The x-ray examinations were not quite so puzzling to Dr. Hampton and to me as they appeared to be at the time of the conference. In fact, Dr. Hampton thought that appendix abscess explained the situation better than any other diagnosis. After the febrile reaction had quieted down, there was a very definite, although ill defined, mass which could be felt bimanually in the right side of the abdomen, and the patient was discharged with a diagnosis of appendicitis with peritonitis, to return for deliberate appendectomy after four weeks.

The findings at operation are not described well in the abstract, owing, I am sure, to our own carelessness in dictating the operative note. The Meckel's diverticulum was not adherent to any structure, it had no appearance whatever of acute inflammation, and the fact that it was found acutely inflamed by pathological examination does not indicate that this had anything to do with the acute episode six weeks previously. The appendix, however, was lying in the pelvis next to the rectum and was adherent to it, and when it was elevated out of the pelvis, it was obvious that we were freeing fresh, more recent adhesions. The distal half of the appendix was thickened and reddened, and appeared exactly like many I have removed several weeks after a known acute inflammatory attack.

There was no doubt whatever in my mind or in my assistant's mind that the appendix had accounted for the patient's acute attack and that the Meckel's diverticulum was, in fact, an incidental finding.

The patient's convalescence after operation was identical with the type that goes with an appendix removed under these circumstances; in other words, there was more febrile reaction than in the removal of an interval or normal appendix, and considerably more ileus than is usually seen. This might have been due to the added removal of the Meckel's diverticulum, but I believe is more likely to have been due to the stirring up of the quiescent infection in the pelvis.

THE ONE-DAY CURE FOR SYPHILIS

It is surprising that the *Reader's Digest*, which renders a notable service with its excellent summaries of current magazine articles and new books, should publish for lay consumption an article* on a new one-day cure for syphilis as if the procedure were already available for every physician to use as safe and scientific on any and all patients with syphilis.

Such an ill-advised statement has raised many false hopes and disturbed many patients who are progressing satisfactorily under treatment. It has instigated many queries to physicians and medical journals about a method that is still in the experimental stages. The method has very definite

hazards. Not everyone can tolerate a fever of 106°F., and patients with certain defects should never be exposed to such a temperature. The apparatus and controls are not at hand. Neither physicians nor nurses have had sufficient training in the method. Too few cases have been treated and too short a time has elapsed to know if there are any late serious effects of the treatment and if the results on the disease are permanent. It may be a step forward in the treatment of syphilis, but much experimental work must be done to be sure that this particular technic is the proper procedure for every case of syphilis. There are many pitfalls in this complicated program, and it is cruel for a scientifically trained writer to propose such a method to the public as accepted and readily available in every city and town. Furthermore, why did this writer pick out an eleven-year-old article to stress the bad effects of routine anti-syphilitic treatment? In a letter published in the September 19 issue of the *Journal of the American Medical Association*, Dr. Harold N. Cole, a distinguished syphilographer and the author of the former article, emphasizes the bad effects of publicizing prematurely an experimental procedure that needs confirmation before it is widely available for syphilis in general.

Physicians can assure their questioning patients that the one-day treatment is in the experimental stage and is not a safe and sure procedure and that it will eventually be made readily available if scientific evidence warrants its acceptance. Incidentally, one cannot refrain from suggesting that the publication of medical articles in a periodical for lay consumption is a great responsibility and one that cannot be discharged properly without the aid of competent medical opinion.

GUIDES TO THERAPY FOR MEDICAL OFFICERS

AN excellent pocket-sized technical manual, entitled *Guides to Therapy for Medical Officers*,† has recently been issued by the War Department. As

*de Kruif, P. Found: a one-day cure for syphilis. *Reader's Digest*, September, 1942.

†War Department. Technical Manual 8-210. *Guides to Therapy for Medical Officers*. 185 pp. Washington: Government Printing Office, 1942.

stated in the opening paragraph, the purpose of this manual is to provide the medical officer with a handy text containing guides to therapy under emergency conditions or in diseases with which he is relatively unfamiliar. The accepted treatment of the diseases commonly encountered in civilian life is not discussed, nor are such topics as the control of communicable diseases and sanitation. In other words, it is intended to serve as a guide to the "general practitioners" of the Army and not as a text for specialists, who are likely to be stationed with evacuation units or in general hospitals. It is also emphasized that the text does not comprise rules and regulations that must be followed, but merely suggestions to be used at the discretion of the medical officer.

The manual is well conceived and carefully executed. The Surgeons General of the Army and Navy, early in 1940, requested the Division of Medical Sciences of the National Research Council to establish committees that should act in an advisory capacity to the two medical corps. Much of the text of this manual is based on material compiled by these committees. Final revision was conducted by pertinent divisions of the Office of the Surgeon General, United States Army. The manual was edited by a member of the Committee on Information of the National Research Council.

The reports of the many experts are presented in an easily readable, compact and orderly fashion. The major subjects covered are as follows: surgical emergencies; medical emergencies; diagnosis and treatment of venereal diseases; chemotherapy and serotherapy in certain infectious diseases; and rickettsial diseases. The contributors to each of these sections include many of the leading names in American medicine and surgery.

Under surgical emergencies are included the commonest types of wounds in various parts of the body, the management of shock and the early treatment of burns. Most of the essential details are given, but the specialized forms of treatment that can be undertaken only by experts are almost entirely omitted. The section on medical emer-

gencies covers the majority of situations that might arise under the great variety of conditions to which troops are likely to be subjected, including such diverse items as acute poisoning from various foods, chemicals, plants and animal sources, sea-sickness, altitude sickness, the effects of exposure to heat and cold, starvation and the acute psychoses. The sections on tropical and rickettsial disease are meant to acquaint medical officers with conditions that are rarely encountered in civilian practice but that are very likely to be met with in the far-flung regions where troops may be operating. Each section is preceded by a table of contents, and there is a well-arranged and easily usable index at the end of the volume.

The manual seems well suited for the purposes for which it is intended. In fact, it could advantageously serve as an abbreviated and handy text for general practitioners and for medical students and hospital interns who are likely to see active military service in the near future. It is likewise suitable as a "procedure book" for use in the emergency rooms of general hospitals. No doubt, the manual will be kept up to date when reprinting becomes necessary. It can be obtained for twenty-five cents from the Superintendent of Documents, Washington, D. C.

MEDICAL EPONYM

SCHICK TEST

This was first described by Dr. Béla Schick (1877), then private docent in the clinic of Professor von Pirquet in Vienna, in an article "Die Diphtherietoxin-Hautreaktion des Menschen als Vorprobe der prophylaktischen Diphtherieheilseruminjektion [The Diphtheria-Toxin Skin Reaction in Man as a Preliminary Test in the Prophylactic Injection of Diphtheria Antitoxin]" in the *Munchener medizinische Wochenschrift* (60²:2608-2610, 1913). A portion of the translation follows:

For intracutaneous injection, the ordinary 1-cc. Reckord syringe marked in tenths is needed. The most important part is the needle, which . . . should be as fine as possible, with a short bevel, in order that the opening of the needle may be covered as quickly as possible when it is introduced into the most superficial layers of the skin. A dose of 0.1 cc. of a dilution of the toxin, which must be calculated in each case is

given. As a rule, one fiftieth of the minimal lethal dose for a 250-gram guinea pig suffices — for example, with a lethal dose of 0.005 cc. for a 250-gram guinea pig, an injection of 0.1 cc. of a 1:1000 dilution. If the injection is successful, there is at once apparent a white wheal-like elevation with dots corresponding to the orifices of the hair follicles.

The changes that occur at the site of injection of the diphtheria toxin resemble in appearance those occurring during the first twenty-four to forty-eight hours of a positive tuberculin reaction. . . .

A negative response to the intracutaneous test always indicates the presence of diphtheria-toxin antibodies in sufficient amounts for prophylaxis. . . . A positive test does not indicate their absence with the same certainty, since many individuals, children as well as adults, may show an inflammatory reaction at the site of injection of diphtheria toxin in spite of the presence of protective substances in their serums.

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE ON MATERNAL WELFARE

ANALYSIS OF CAUSES OF MATERNAL DEATH IN MASSACHUSETTS DURING 1941

PNEUMONIA

As the tabulation of medical causes of maternal death printed in last week's issue of the *Journal* shows, pneumonia ranked second to heart disease as a fatal complication of pregnancy. There were 12 cases in which this disease was the primary cause of death during 1941: in 7, the infection followed normal delivery; in 3, the patients died undelivered; and in 2, there had been an operative delivery. Autopsies were performed in 5 cases.

Of the 7 associated with normal delivery, the first case was that of a patient who developed pneumonia on the third post-partum day and died three days later. Autopsy revealed a normal pelvis and bronchopneumonia of the influenza type.

The second patient, when five and a half months along in her second pregnancy, developed pneumonia; a spontaneous abortion occurred the day after hospital entry. The infection was due to a Type 22 pneumococcus, and in spite of sulfonamide and serum therapy, death occurred the following day.

The third patient developed a fever thirty-six hours post partum. Blood cultures were negative; the patient was given sulfathiazole and transfused; a clinical diagnosis of pneumonia was made and confirmed at autopsy.

The fourth patient entered the hospital at term with an acute upper respiratory infection. She had a normal, rapid delivery but died on the tenth post-partum day, autopsy proving the cause of

death to be bronchopneumonia and pneumococcal septicemia.

The fifth patient, who had had thirteen previous pregnancies, entered the hospital cyanotic and with a pulse rate of 140. Ten hours after entry, she delivered herself of a 2-pound infant, and lived but thirty-four hours post partum. A diagnosis of pneumonia was confirmed at autopsy.

The histories of the last two cases in this group are incomplete. One of them entered the hospital with influenza and died during delivery. The other case was that of a patient delivered at full term of a living child who died a few days after delivery.

Of the 3 cases allocated to pneumonia who died undelivered, the first was that of a patient, five months along in her third pregnancy, who died four hours after admission to the hospital.

The second patient entered the hospital at term with acute bronchopneumonia. She had had a cold for three weeks and died undelivered three days after entry. An autopsy was performed, and death was found to be due to bronchopneumonia.

The third patient was a woman who, in the seventh month of her third pregnancy, had called her physician because of a severe cold of three days' duration. She was sent to the hospital, and a diagnosis of bronchopneumonia made by x-ray study. Death occurred four days after entry, and a living child, weighing 6 pounds, 3 ounces, was delivered by post-mortem cesarean section. The causative organism was a Type 3 pneumococcus.

The remaining 2 cases were patients who were delivered by operative intervention. The first case was handled unintelligently: after a sixty-hour labor and an unsuccessful attempt at high-forceps delivery, a cesarean section was done. Pneumonia developed postoperatively. This, of course, was an unjustifiable death.

The second patient was delivered by low forceps. There is no evidence in the record that pneumonia was present at the time of delivery, but two weeks afterward x-ray films showed a bilateral lobar pneumonia, from which she did not recover.

It is very gratifying that only one of these cases was a postoperative pneumonia and that this was the only case associated with unintelligent obstetrics. Those patients who died undelivered emphasize particularly the seriousness of pneumonia as a complication of pregnancy. It must be borne in mind that a cold may develop into bronchitis and bronchitis into pneumonia, and that during pregnancy the patient with a common cold must be treated more conservatively than she would be if she were not pregnant. The attending physician should be notified immediately, and rest in bed should be ordered. A cold accompanied by a fever

requires medical examination. Although chemotherapy and serum treatment have undoubtedly reduced the mortality from pneumonia, both methods to be successful require early diagnosis. Only closest possible co-operation between the physician and the patient will make the treatment of pneumonia as successful as it should be.

DEATHS

ADAMS—**CHARLES W. ADAMS, M.D.**, of Cambridge, died October 20. He was in his sixty-fourth year.

Dr. Adams received his degree from Harvard Medical School in 1905 and was a member of the Massachusetts Medical Society and the American Medical Association.

His widow survives him.

COON—**WILLIAM H. COON, M.D.** of Laston, Connecticut, died October 6. He was in his sixty-eighth year.

Dr. Coon received his degree from Bellevue Hospital Medical College, New York, in 1897. He had served as assistant physician at the Northampton Insane Hospital, as house officer at the Boston City Hospital, as executive officer of the Harvard Infantile Paralysis Commission, and as health commissioner of Bridgeport, Connecticut.

He was a former member of the Massachusetts Medical Society.

His widow, a son and a daughter survive him.

GREENWOOD—**ALLEN GREENWOOD, M.D.** of Boston, died October 23. He was in his seventy-seventh year.

Born in Chelsea, he received his degree from Harvard Medical School in 1889 and served his internship at the Boston City Hospital. Dr. Greenwood was professor of ophthalmology, emeritus, at Tufts College Medical School and lecturer on ophthalmology in the Courses for Graduates, Harvard Medical School. He was affiliated with the Boston City Hospital, the Massachusetts Eye and Ear Infirmary, the Beth Israel Hospital, the New England Hospital for Women and Children, Adams House, the Waltham Hospital, the Milford Hospital and the Framingham Union Hospital.

Dr. Greenwood was a fellow of the Massachusetts Medical Society and the American Medical Association. He held memberships in the American Academy of Ophthalmology and Oto-Laryngology, the American Ophthalmological Society, of which he was a former vice president, the Association for Research in Ophthalmology, the New England Ophthalmological Society and the American College of Surgeons.

His widow, two daughters and a son survive him.

WALKER—**HARRY A. WALKER, M.D.**, of Somerville, died October 30. He was in his sixty-second year.

Born in Binghamton, New York, he received his degree from Cornell University Medical College in 1905. He served for four years in New York hospitals before moving to Somerville, where he was a member of the staff of the Somerville Hospital.

Dr. Walker was a fellow of the Massachusetts Medical Society and the American Medical Association. He was a member of the Somerville Medical Society, the Cornell Medical Alumni, and the Cornell Club of New England.

His widow, a son, and two daughters survive him.

WAR ACTIVITIES

SELECTIVE SERVICE

The following announcement by the Massachusetts state director of selective service is of general interest.

* * *

It has been decided by National Headquarters, Selective Service, not to extend the program of physical rehabilitation. Further activity relative to this program has been discontinued so far as the Selective Service System in Massachusetts is concerned. The names of those physicians, dentists and institutions who have signified their willingness to participate in a program of rehabilitation will be kept on file at State Headquarters.

This is not intended to affect or interfere with projects or programs for rehabilitation of Selective Service registrants on the part of groups or organizations not directly connected with Selective Service.

Local board examining physicians have been asked to exercise discretion in utilizing the services of examining dentists in the physical examination of selectees. Dental diseases or defects are no longer shown as a cause for rejection by local board examining physicians. Hence the desire to conserve the time and energy of examining dentists who have been so faithful and loyal in their efforts to make a contribution to Selective Service in the field of dentistry. Some local boards have utilized the services of examining dentists in some capacity outside dentistry. This of course permissible and it is not meant that such activities or help is to be dispensed with.

Examining physicians in full co-operation with their local boards are now engaged in reviewing the cover files of all registrants who have been placed in Class IVF because of some physical disqualification. They have been called on to exercise sound medical judgment in studying these records so that those registrants who are hopelessly disqualified for all military duty will be kept at home and all others who are qualified for full or limited military duty will be sent to the induction station.

A study of registrants in Class IVF because of a mental or nervous disorder is about to be undertaken. It will be confined to groups of ten or fifteen registrants from each of fifteen local boards scattered throughout the State urban and rural areas included. The purpose of this study is to determine what proportion of the registrants in this group are qualified under present standards, for full military duty as well as to discover what number if any now disqualified for military duty are fit subjects for psychiatric or other methods of rehabilitation.

Recently local boards were directed to begin immediate preliminary reclassification of all married men with wives only. This is of immediate and pressing interest to those members of the medical profession who are now in Class IIIA either because of collateral dependents or because they are married and have no children. The demand for medical officers in the armed forces is insistent; it is pressing; it is imperative. Medical men in the two categories named above who have been declared by the Procurement and Assignment Service to be available for military duty should apply at once for a commission through the Medical Officers Recruiting Board, 319 Longwood Avenue, Boston. There is always a chance of delay in processing the papers. Occasionally x-ray and other studies are necessary. Local boards are no longer permitted to defer the induction of a registrant so that he may apply for or await the processing of an application for a commission. If a medical man has delayed in ap-

plying for a commission and his order of induction has been issued, he may be inducted and have to serve as an enlisted man before the commission catches up with him.

As the need for medical men in the armed services is becoming more generally recognized, there has been a noticeable stiffening in the attitude of Selective Service officials toward members of the medical profession who have been declared available for military duty yet who refrain from taking the necessary steps until it is almost too late. National Headquarters, Selective Service System, in Local Board Release, No. 89, has said, in part:

In considering the classification of a registrant who is a qualified medical doctor, dentist or doctor of veterinary medicine, the local board may, if it finds such registrant should not be deferred for reasons other than dependency, take into consideration the pay and allowances which such registrant would receive in the event he is commissioned in the armed forces. In practically all instances the pay and allowances of such registrant, if he were commissioned as an officer, would be sufficient to eliminate the question of dependency.

In this connection, it may be said that it is probable that Selective Service will begin inducting men with dependent wives in the very near future, possibly in November or December, 1942.

If a registrant applies for a commission and he is refused, either because he is found physically disqualified or for any other reason, local boards have been asked to consider classifying him in either IVF or IIA. Class IVF will be restricted to those registrants whose physical examinations by the Medical Officers' Recruiting Board reveal the presence of a physical defect which would normally cause rejection at the induction station.

Students in accredited medical, dental or veterinary schools may apply for a commission in the Medical Administrative Corps as soon as they have been admitted to the freshman class. Local boards have been asked to consider for occupational classification (Class IIA) students who are in good standing in a medical, dental or a veterinary school, as well as those who are in an osteopathic school. This is on the theory that such students are in training for an occupation necessary in the national health, safety or interest.

MISCELLANY

PULMONARY TUBERCULOSIS AMONG SPANISH-SPEAKING PEOPLE

To meet the menace of a rise in the tuberculosis death rate due to war conditions, a renewed emphasis must be laid on special problems in the fight to control and ultimately to eradicate the disease. It is timely and pertinent to call attention to certain of these problems in which assistance of the general medical profession is indispensable.

Industrial problems and racial problems stand out clearly against the background of national health, which is threatened by the exigencies of war. A cogent article (Wilson, W. J. Pulmonary tuberculosis among the Mexican population of Weld County, Colorado. Rocky Mountain M. J. 39:432, 1942) is illustrative of the situation existing in various parts of this country, one which can only be met by concerted action on the part of the medical profession.

The problem in Weld County, Colorado, differs in extent but not in kind from countless similar ones that confront physicians throughout the country.

* * *

It is a well-established fact that the incidence of pulmonary tuberculosis varies markedly in different races. Roughly, there appears to be an increase in incidence as the pigmentation of the skin characteristics of the race increases, and also an increase with the magnitude of climate change occurring when the darker-skinned races migrate to colder regions. Thus, a native of the tropics coming to Colorado to live is more liable to contract tuberculosis than a native Coloradan. Whereas the present death rate for tuberculosis in the United States Registration area is approximately 36 (in 1940) per 100,000 population in Whites, the rate for Negroes is almost three and a half times that number.

The incidence of tuberculosis in the Mexican falls between the rates for Negroes and Whites. However, reported figures have shown fairly wide variations. These variations are to be expected, since the Mexican who was born and raised in the Rio Grande valley and who later moves across the river into the Texas side of the valley has made no change in climate at all, but the Mexican who migrates from Monterey to Colorado has made a very decided change. It is therefore expected that the incidence of tuberculosis among Mexicans coming to Colorado will be greater than that among those stopping in southern Texas, New Mexico and Arizona.

The Weld County study, under the joint sponsorship of the Weld County Tuberculosis and Health Association and the Weld County Health Department and Public Health Laboratories, shows the tuberculosis problem that exists among the several thousand Mexicans residing in this Colorado county. Nearly all of them are occupied in farm work, mainly the planting and harvesting of sugar beets. Over half of them live in "Spanish colonies." Living conditions are quite uniformly substandard and crowded. This undoubtedly contributes in no small measure to the picture presented by this study.

During the thirty-month period from September 1, 1939, to March 1, 1942, a case-finding program was carefully conducted among the Mexican population of Weld County. A total of 1745 persons were tuberculin tested, and all positive reactions followed up with an x-ray examination. Of the reported studies, very few have contained complete follow-ups of all positive reactors. The Weld County study is now complete except for the progress following diagnosis and treatment of all active cases found.

The tests were made, for the most part, in "Spanish colonies" after showing a series of educational films produced by the National Tuberculosis Association. The interest response was very gratifying, and all age groups attended, as is shown in the figures of Table 1. The ages ranged from less than two years to over seventy.

The remainder of the persons included in the study were segregated from the testing programs carried on in the schools of the county, and a few persons who were tested for various reasons. On the whole, the group studied should represent a very nearly accurate cross section of the Mexican population of the county.

Of the 1745 persons tuberculin tested, 745, or 42.7 per cent, had positive reactions. These 745, along with forty other persons from families in which active tuberculosis was found, were given chest x-ray examinations. These forty people had not had previous tests.

In 481 of the chest x ray films, there was no evidence of tuberculous activity and they were dismissed from further study

In 304 cases, radiographic evidence ranged from merely suggestive to definite evidence of disease. These were referred to the Chest Clinic of the County Health Department for further study, including physical examination, sputum examinations and cultures. Sixty-one persons were found to have active pulmonary tuberculosis. Of these, 51 had far advanced disease, 4 had moderately advanced disease, 4 had unusual lesions and 2 refused to co-operate.

Based on this study, the incidence of tuberculosis among the Mexican population of Weld County is found to be the staggering figure of 34.17 per 1000 population — Reprinted, in part, from *Tuberculosis Abstracts*, October, 1942

NOTE

The Salem Tumor Clinic held a teaching clinic at the Salem Hospital, on Friday, October 30, with Dr George W. Holmes, professor of radiology at Harvard Medical School, as the speaker. Dr Holmes spoke on General Aspects of Irradiation in Carcinomas

CORRESPONDENCE

CAROTID-SINUS REFLEX

To the Editor In an article published in the September 24 issue of the *Journal*, entitled "The Significance of the Carotid Sinus Reflex in Biliary Tract Disease," by Engel and Engel, the authors offer some interesting observations. However, their conclusion that a hyperactive cardioinhibitory carotid sinus reflex in cases of biliary tract disease is due to sensitized nervous pathways is not warranted from their limited observations. Do they imply by sensitized nervous pathways a lowering of the synaptic resistance in the vagal center, in the ganglia of the heart or in the resistance offered by the myoneural junctions of the vagus? Or, do they mean a hypersensitivity of the vagus nerve? Furthermore, what brings about such a state? Is it due to a chemical substance elaborated by the disease or to some reflex factor that summates with the impulses coming from the carotid sinus region? In the latter case one should not consider it sensitization, but summation.

From a physiologic viewpoint, coronary disease meaning not merely coronary sclerosis but also coronary insufficiency, may explain a hyperactive cardioinhibitory carotid sinus reflex even in the authors' few cases. All physicians are familiar with the anginal syndrome induced by biliary tract disease in some patients, especially in the older age groups where coronary sclerosis is usually present. The authors themselves observed it in some of their cases. It is also now generally agreed that the anginal syndrome is due to acute coronary insufficiency caused by increased heart activity during effort or excitement, or by reflex angiospasm of the coronary vessels. It can therefore be readily understood how acute biliary tract disease may produce coronary angiospasm and resultant coronary insufficiency by impulses set up in the interconnecting vagosympathetic system of the abdominal organs and a lowering of the resistance of the myoneural connections and of the ganglionic synapses of the vagus nerve in the heart.

It is interesting to find that all the authors' 18 patients who presented a positive carotid sinus cardioinhibitory reflex were over forty-one years of age, and most of them

over fifty, when coronary sclerosis detectable or not detectable by clinical or laboratory means is to be expected. The potentiality for an acute coronary insufficiency to develop in such cases under any provocative factor is always present.

It would be interesting to learn how many patients less than forty years of age exhibit the anginal syndrome and the hyperactive cardioinhibitory reflex in biliary tract disease. The fact must be appreciated, however, as I have brought out in my papers to which the authors refer, that the hyperactive cardioinhibitory carotid sinus reflex often occurs also in the absence of coronary disease, probably owing to a constitutional weakness in the synapses, which lowers their resistance.

The authors are wrong in their implication that I advocate the hyperactive cardioinhibitory carotid sinus reflex as the sole diagnostic factor in coronary disease. I suggested its use merely as corroborative evidence in patients who present clinical evidence suggestive of the presence of coronary disease. As such it is occasionally of greater value than the electrocardiogram, and is oftener positive.

Those who have had sufficient experience in electrocardiography know full well the limitations of the electrocardiogram as a diagnostic means.

Brooklyn

POLITICAL RESPONSIBILITY OF PHYSICIANS

To the Editor Physicians are not properly represented in the legislative bodies of our cities, states and the Nation. Members of all other occupations, business and professional, are elected to office. Since physicians are not stepchildren they, likewise, should have adequate representation. I have often and in various ways, at Council and district meetings, tried to exhort, enthrill and encourage physicians to make the sacrifice to become candidates for the Legislature. Indeed, at the recent primaries, after having failed to persuade a single physician to become a candidate, I was finally persuaded to seek the nomination in my district. Since compulsory state medicine is a possibility and since other important medical matters are scheduled to appear before the Legislature, Congress and the courts, it has become absolutely necessary that physicians should take part as members of the law-making bodies.

The National Physicians' Committee, whose work and activity were approved on June 9, 1942, by the House of Delegates of the American Medical Association, has exposed the existing conditions of medicine. We pay taxes and do millions of dollars' worth of careful and faithful work for the poor (and even for many who can afford to pay us, and do not), but no one is taking our part, we certainly do not merit the treatment we are receiving from politicians and the public.

Laymen seem to think that they must have lawyers in the law-making bodies. Of course, they are wrong, but it is up to us, who protect their health, to make them pay a little attention to our ideas. When an organization comes annually to the State House and wants to repeal the vaccination law and another wants to prevent us from using animals for experimentation (at one session, this was up for a second hearing), it is high time that we should protect the population and ourselves by having our own representation.

If compulsory state medicine is passed, the politicians will be in control and will order physicians around. The fine relations that exist between patients and physicians will disappear. Progress and advances in medicine will cease, and chaos will arise. Perhaps some physicians will benefit by this for they will work short hours and receive a fair salary.

Compulsory state medicine would take in hospitals, physicians, nurses, pharmacists and everything else that has to do with medicine. This would involve an expenditure of somewhere in the region of \$3,500,000,000 to \$5,000,000,000 (which would be controlled by politicians). Physicians must take a determined interest in this matter and definitely express an opinion. California has already defeated such a measure—physicians, hospitals, nurses and pharmacists must awake and act, not tomorrow but now.

Since the Massachusetts Medical Society has just started a plan that will eventually, I trust, take care of the complete cost of adequate medical care, there seems to be little excuse for compulsory state medicine. If we, as physicians, take heed at this time and pay attention to the advice of the American Medical Association and of the National Physicians' Committee to take our own part, we can benefit, and any proposed bill to inaugurate compulsory state medicine can be defeated.

REPORT OF MEETING

WILLIAM HARVEY MEDICAL SOCIETY

The season's first meeting of the William Harvey Medical Society of Tufts College Medical School was held at the Beth Israel Hospital on September 25, with Dr. A. Warren Stearns presiding. The speaker of the evening was Dr. Alan Moritz, professor of legal medicine at the Harvard Medical School, and his subject was "Distinguishing Characteristics of Forensic Pathology."

In contrast to the ordinary hospital postmortem, the medicolegal autopsy is usually of immediate importance to some living being; in fact, it may determine the life or death of such a person. It may also serve to place great financial liability. The hospital postmortem, on the other

hand, usually has only educational value. The medicolegal autopsy, furthermore, is frequently contested hotly by one or several "experts," whereas when the hospital pathologist gives his opinion it is usually considered final.

One of the problems of forensic pathology not ordinarily met by the hospital pathologist has to do with identification. Strange as it may seem, there are an astounding number of missing persons at any one time, and the lack of interest on the part of relatives and friends may be a great handicap. Often nothing but a skeleton is found, and even bones of bears and the primates have sometimes been confused with those of human beings. The roentgenologist is often of inestimable value in determining the identity of an unknown skeleton. Often age can be fairly accurately computed from the character of the epiphyses. The height may be estimated by Pearson's formula, even though only the humerus or femur is available. Sex may usually be recognized from the clothing and, failing that, from the character of the pelvis and other bones. The approximate weight of the individual is somewhat more of a problem, but can sometimes be estimated from stature and clothing.

Information regarding the time of death is frequently of inestimable value in ruling out certain persons in a suspected crime. One cannot always accurately determine the exact time of demise, but it is often sufficient to place the time within a few days or even within a certain month. Specimens taken from different areas of injury may confirm the suspicion that the wounds are of different ages, that is, that some were inflicted an appreciable time before death. A botanist may aid by determining how long a plant or bush has been crushed beneath a body, and an entomologist may add some information by judging the age of the eggs of vermin found devouring a body. Either may place time of death within a two-week period and thus incriminate or free a suspected person.

The medicolegal pathologist must develop a suspicious mind and never be satisfied with the plausible cause of death. An example was cited where a man known to have coronary disease was found dead with no evidence of external violence. A complete autopsy, however, revealed a recent large subdural hematoma underlying a bruise of the scalp, which had been covered by his bushy hair. To determine whether or not a death is accidental is often of extreme monetary importance to the relatives of the deceased. There are many places in the body where external violence may be easily missed or where the latent period between injury and death may be long enough to allow healing of the external wound. On the other hand, death from coronary infarct or cerebral accident may be complicated by the finding of signs of external violence that are, in reality, secondary to a fall.

A knowledge of the fundamentals of firearms is almost a prerequisite for a good forensic pathologist, since it is often his duty alone to call attention to some irregularity in the death of a person who has been shot. Such acuity may result in a decision that the shooting was accidental rather than a homicide. The pathologist may be the only one responsible for collecting bullets or other material that may serve to determine the origin of the ammunition and the gun. Ballistics experts are valuable in identifying the gun in question. The character of the combustion residue on the hand or clothing of the deceased may be an important clue in a question of suicide or homicide, and the amount and distribution of powder around the wounds of entrance are of great value.

CHOLANGIOGRAPHIC ARTIFACTS RESEMBLING COMMON-DUCT STONES

HOWARD M. CLUTT, M.D.* AND LIEUTENANT KNOWLES B. LAWRENCE, M.C., A.U.S.†

BOSTON

WHENEVER the common bile duct is opened for exploration during the course of operations for gallstones, it is drained with a T tube. In every case, the problem of when to remove this tube must be settled on certain objective facts, which in their entirety show that the common bile duct is patent and contains no residual or overlooked calculi.

For many years, surgeons depended on the clinical findings following the clamping of the T tube for the decision that the common duct was free and clear of stones. Thus, on the fifth or sixth postoperative day, the T tube was clamped off and the results were carefully observed. If no pain or colic occurred, and if no bile drained around the sinus tract, one was relatively certain that the common bile duct was patent. Usually, the tube was clamped off for six or eight days to prove this point, and then, on the twelfth postoperative day, it was removed.

Unfortunately, it is true that a stone may be left in the common duct and yet may give no clinical evidence of its presence during the time the T tube is clamped off. To avoid this trouble, visualization of the common bile duct by the injection of a radiopaque substance through the T tube and the taking of quick x-ray films^{1, 2} has been developed in recent years as a means of gaining further objective information regarding the patency of the common duct. These postoperative cholangiograms have proved to be highly reliable, and on our service, we routinely visualize all common ducts after T tube drainage before removing the tube.

Fluoroscopic studies and roentgenograms of the common bile duct may demonstrate the following findings.

Normal.

Filling or partial filling of a normal biliary-duct system.

Passage of the opaque medium through the ampulla of Vater, which either is patent at the time of injection or becomes so shortly thereafter by relaxation of its muscular sphincter.

Abnormal

Dilatation of the biliary-duct system

Presence of a foreign body, notably a residual calculus, shown by positive or negative shadows

Failure of the opaque medium to enter the duodenum owing to an obstructing calculus or a persistent spasm of the sphincter of Oddi.

We have believed that a filling defect in the common bile duct as shown in cholangiograms meant that a stone had been left behind, and subsequent events have generally confirmed this belief. This has necessitated the use of the Best-Hicken³ regime to relax the sphincter of Oddi in a few cases. In others, we have successfully followed Pribram's⁴ suggestion for dissolving residual cholesterol stones by washing out the common duct with ether. In only the rarest case has reoperation for these stones been necessary in our experience in recent years.

In four recent postoperative cholangiograms, however, we found a filling defect in the common duct close to the lower end of the T tube that was suggestive of a residual stone but was demonstrated, on further study in each case, to be an artifact. In none of these cases had stones been present in the duct at operation. This fact first aroused our suspicion that the x-ray picture might be due

*Professor of surgery, Boston University School of Medicine, surgeon in chief, Massachusetts Memorial Hospitals

†Assistant in surgery, Boston University School of Medicine and assistant surgeon, Massachusetts Memorial Hospitals (on leave of absence)

to something other than stone. Hicken et al.⁵ mention cholangiographic filling defects in the common duct, apparently due to floating clots and air bubbles, although these were different from those we have noted.

A clot of old blood, bile and mucus clinging to the lower end of the T tube was found to be the cause of the filling defect in 3 cases, as demon-

If one is convinced that the filling defect is due to such an artifact, because of the appearance described, removal of the tube without further procedure is probably justified. If the tube is removed gently and without rotation, the clot or part of it may still be clinging to its lower end, when brought into view. The safer procedure, however, is to irrigate the T tube periodically until

FIGURE 1. Case 1: Cholangiograms on Various Days.

This patient had a postoperative blood clot in the common duct. Note the variations in the shapes of the filling defect from day to day, with no change in its relation to the end of the T tube. There is a long streak-like filling defect in the first film, which probably represents a mucous streamer from the clot. Note the reduction in the size of the defect.

strated on removal of the tubes. This was confirmed by the smooth recovery of the patients. In 1 of these cases, repeated cholangiograms demonstrated a diminution in the size of the filling defect over several days, probably as a result of the mechanical irrigation of the tube. The clot did not obstruct the flow of bile in any of these cases, and colic was not produced.

The features of this type of cholangiographic artifact that helped in the differentiation of the adherent clot from actual stone, or from other solid foreign bodies in the common duct, were as follows: the filling defect appeared in direct, or nearly direct, contact with the lower end of the T tube; the defect changed in shape in serial roentgenograms because of the malleability of the soft clot by action of the bile current, of the injected radiopaque medium or of the local-duct contraction or relaxation; close examination of the x-ray films revealed streaklike defects extending from the principal filling defect several centimeters distally in the duct—this appearance was probably produced by streamers attached to the main clot; irrigation through the T tube and the injection of the opaque medium apparently washed part or all of the clot from its attachment to the tube, and thus changed the appearance of the filling defect in subsequent films.

repeated cholangiograms no longer demonstrate the filling defect, or until it is apparent that the defect is not caused by a retained common-duct stone.

The following is a typical case.

CASE 1. C. W., a 58-year-old man, had suffered with attacks of biliary colic for a year. Cholecystograms showed gallstones. One month before admission, coincident with such an attack, the patient became jaundiced.

Operation was performed on January 19, 1942. A chronically inflamed gall bladder containing several small mulberry-type stones was removed. The common duct, which was three times the normal diameter, with inflamed and thickened walls, was explored and found empty, and the sphincter of Oddi was apparently patent. A T tube was sutured into the duct for drainage.

The postoperative course was uneventful. The T tube was clamped off on the 5th postoperative day. On the 10th day, a cholangiogram was done by injection of lipiodol through this tube. X-ray study demonstrated a rounded defect in the common duct, just beyond the lower end of the T tube (Fig. 1). The lipiodol seemed to have flowed around it readily enough, and passed into the duodenum after a short delay. On re-examination 3 days later, the defect, although still in the same position, was much smaller. The T tube was irrigated with physiologic saline solution. In a third cholangiogram, after another 48 hours, however, the defect showed little further change in size. It was then considered safe to remove the T tube because of the cholangiographic appearances described above—that is, the variation in shape of the filling defect,

the diminution in its size after simple irrigations, the nearly constant positional relation to the lower end of the T tube and the streamer defect noted in the first cholangiogram. On removal of the T tube, directly after the

seemed to show further air shadows surrounding the upper arm of the T tube. Two days later, another cholangiogram was made and more negative shadows were found. The previous shadows were absent. At each injection,

FIGURE 2 Case 2 Cholangiograms

The air bubbles in these films resemble common duct stones. Note the air around the arms of the tube, the changing size and symmetry of the bubbles and the rapid and ready emptying of lipiodol into the duodenum.

third cholangiogram, a soft bile stained clot of blood and mucus was found clinging to the lower arm of the tube at its tip. This measured about 5 mm. in greatest diameter. The sinus drained bile for about 36 hours, and then stopped. The patient has remained asymptomatic since that time.

Air bubbles may be present in the common duct and may give a shadow very suggestive of a smooth, oval, residual stone. These air bubbles are said by x-ray men to be the commonest artifact seen in postoperative choledochograms, but this has not been our experience. We have recently had a case, however, in which we found it difficult to convince ourselves that the stone like shadows seen following postoperative common duct injections were air bubbles and not stones.

CASE 2 At operation, the gall bladder was found much thickened and chronically inflamed. It contained one large stone, which was removed, exploration of the common duct revealed no stones. On the 5th or 6th postoperative day, the T tube was clamped off, with no untoward results. On the 12th day, choledochograms (Fig 2) were made. In these x-ray films, negative shadows just below the lower arm of the T tube were noted. Close inspection

it was noted that the lipiodol flowed readily and freely into the duodenum. The T tube was removed after the second x-ray examination, and bile drainage from the sinus ceased in a few hours. Recovery was uneventful.

In this case, it became apparent that the negative common duct shadows were air bubbles and not stones because of their change in size and position and because of the other evidences of air around the arms of the T tube. In this and similar cases, however, it is apparent that repeated cholangiograms should be made to prove that the shadows in the common duct are not stones but artifacts.

SUMMARY

Artifacts simulating common bile duct calculi after choledochostomy and observed in postoperative cholangiograms are described.

The filling defect in 3 such cases was due to a clot of blood, bile and mucus clinging to the lower end of the choledochostomy tube. In a fourth case, the artifact was caused by air surrounding the T tube.

X-ray films demonstrating these cholangiographic artifacts are reproduced and comments on their proper interpretation are made.

HEMOLYTIC STREPTOCOCCUS BACTEREMIA*

A Report of Thirteen Cases with Special Reference to the Serologic Groups of the Etiologic Organisms

LOWELL A. RANTZ, M.D.,† AND WILLIAM M. M. KIRBY, M.D.‡

SAN FRANCISCO

THE study of hemolytic streptococcus disease has been greatly enhanced by the application of the serologic methods of classification devised by Lancefield.¹ Extensive observations have shown that organisms of Group A are responsible for nearly all the infections of the respiratory tract, such as scarlet fever, tonsillitis, otitis media and pneumonia.^{2,3} Organisms of this group are also responsible for many infections of other organs, particularly the skin and female genitalia. A recent study in this clinic, however, demonstrated that only 25 per cent of the hemolytic streptococci isolated from sources other than the respiratory tract were members of Group A.⁴

It is important to evaluate the nature and severity of the infections caused by the streptococci of these various groups, since their course and response to sulfonamide and other therapy may well be different. For example, a recent study of Group D infections showed that the sulfonamides were without effect,⁵ a conclusion for which there is adequate experimental evidence.⁶

Because invasion of the blood by the hemolytic streptococcus occurs only in conjunction with severe infectious processes,^{7,8} the presence of bacteremia may be used as an indication of the frequency with which members of the various Lancefield groups are responsible for serious disease. An earlier comprehensive study of this problem^{2,9} revealed that 90 per cent of strains of hemolytic streptococci recovered from the blood were members of Group A, but 85 per cent of the cases studied were those of respiratory infection.

Observations in several clinics^{10,11} demonstrate that organisms of Groups B, C and G are responsible for 10 to 25 per cent of all cases of hemolytic streptococcus puerperal infection, and that

approximately 25 per cent of the cases of puerperal septicemia are associated with members of these groups. The prognosis in these cases has been poor, since the disease is severe and endocarditis frequently present.

The purpose of this paper is to emphasize further the fact that hemolytic streptococci of groups other than Group A are frequently the cause of serious infections in man, by presenting a study of 13 consecutive cases of hemolytic streptococcus bacteremia observed in this clinic, in only 6 of which Group A organisms were the etiologic agents. The results of sulfonamide therapy in several of these cases will be described.

It should be emphasized that this study was conducted in a community in which hemolytic streptococcus infections of the respiratory tract are mild and relatively uncommon; that no contagious disease ward is associated with the clinic; and that the majority of the patients are admitted for diagnostic study, elective surgery or normal labor. For these reasons, the character of hemolytic streptococcus infections observed is different from that described in other centers.

The distribution of the organisms isolated from the blood among the various Lancefield groups is as follows: Group A, 6 cases; Group B, 4 cases; and Groups C, D and G, 1 case each. Organisms were isolated only from the heart's blood at autopsy in 4 cases (1 case of Group A, 2 cases of Group B and the case of Group G infection); no ante-mortem blood cultures having been performed.

CLINICAL DATA

Group A

Hemolytic streptococci of Group A were isolated from the blood of 6 patients. These cases, similar to those observed and described previously,⁷ need not be considered in detail.

*From the Department of Medicine, Stanford University School of Medicine, San Francisco.

†Assistant professor of medicine, Stanford University School of Medicine.

‡Assistant resident in medicine, Stanford University Hospitals.

Four patients were treated with sulfonamides. Recovery occurred in a case of pneumonia and empyema in a young woman treated with sulfapyridine, and in another case of pneumonia, complicated by suppurative arthritis in a seventy-year-old man suffering from chronic lymphatic leukemia, who was treated with sulfadiazine. Two patients who received chemotherapy died. One was a young girl with otitis media, osteomyelitis of the temporal bone and meningitis; the other was an elderly man in whom bacteremia complicated an infected ulcer of the leg, associated with congenital hemolytic jaundice. No clinical data were available on one of the 2 remaining cases. The last was an example of acute hemolytic streptococcus peritonitis, which followed an exploratory laparotomy in an elderly man whose liver was discovered to contain metastases from a carcinoma of the stomach. Chemotherapy was not instituted, and the patient died within five days of the onset of symptoms of infection.

Thus, 3 cases of Group A bacteremia associated with disease of the respiratory tract were observed. Recovery occurred in 2 cases in which the primary disease was in the lungs. Meningitis, complicating otitis media, resulted in death in the third. Infections of the skin and of the peritoneal cavity in 2 chronically ill men were followed by death.

This small group of cases does not permit an evaluation of the most effective sulfonamide drug for use in the treatment of serious infections caused by Group A streptococci. The dramatic recovery of an old man, debilitated by chronic lymphatic leukemia and suffering from pneumonia and suppurative arthritis, suggests that sulfadiazine will be found to be an unusually effective agent for the treatment of these infections.

Group B

Four cases of invasion of the blood by Group B hemolytic streptococci were studied. In 1 the organisms were recovered from the heart's blood at autopsy in a man who had died of carcinoma of the lung, and were probably terminal invaders. The other 3 cases are of special interest and are presented in greater detail.

CASE 1. An elderly male diabetic patient entered the hospital with a history of diabetes mellitus for 15 years and a painful left 5th toe for 2 weeks. X-ray evidence of osteomyelitis of the phalanges was present, and the toe was amputated. Three weeks later an abscess of the left foot was drained, and cultures of the purulent exudate showed *Staphylococcus aureus* and hemolytic streptococci, which were not grouped serologically. A guillotine amputation of the left leg in the thigh was performed because osteomyelitis of the metatarsal was discovered to exist. Infection of the stump followed, and the patient died 1 week after operation. Group B streptococci were recovered from

the heart's blood at autopsy. Sulfonamides were never administered.

CASE 2. A laminectomy was performed, and a meningioma was removed from the midthoracic region of a middle-aged woman. Six days after the operation she developed a stiff neck, a positive Kernig's sign and fever. The spinal fluid was purulent, and Group B hemolytic streptococci were recovered from it and from the circulating blood.

Sulfapyridine was administered 24 hours later, at which time the blood culture was sterile and the temperature was lower. The patient recovered uneventfully after 3 days of chemotherapy.

CASE 3. A 30-year-old woman was delivered at term after a 24-hour labor complicated by a transverse presentation of the fetus. The temperature rose within 24 hours to 40°C., and Group B streptococci were isolated from the interior of the uterus. Six grams of sulfanilamide was administered daily for the following 9 days, during which time she remained desperately ill. The first blood culture, obtained on the 8th postpartum day, showed two colonies of hemolytic Group B streptococci per cubic centimeter. The sulfanilamide was immediately replaced by sulfapyridine, and within 49 hours the temperature was normal and the patient made an uneventful recovery.

Thus Group B hemolytic streptococcus bacteremia was observed in 4 cases. In 1 the organisms invaded the blood as a terminal event of another fatal illness. The recovery of Group B streptococci from the heart's blood of a patient with osteomyelitis, in whom cultures of the purulent material obtained from the region of the bone also revealed hemolytic streptococci, suggests that these organisms may have been etiologically related to the suppurative process that eventually proved fatal. It is unfortunate that the streptococci recovered from the local lesion were not classified serologically.

A patient with postoperative Group B streptococcal meningitis and bacteremia recovered following the administration of sulfapyridine. Because the blood had already become sterile and the temperature lower when the drug was first exhibited, it is quite possible that recovery would have occurred in the absence of chemotherapy. This case has been described elsewhere,¹² and it was proposed that infection of the meninges with streptococci not of Group A may account for certain spontaneous recoveries from hemolytic streptococcus meningitis.

The last case in this group is of great interest. Puerperal sepsis caused by Group B streptococci was not associated with endocarditis or the development of local suppuration described by others.¹³ Furthermore, the patient recovered following sulfonamide therapy. Most important, however, is the fact that sulfanilamide failed to exert a beneficial effect on the course of the disease, and the blood was not sterilized, whereas the admin-

istration of sulfapyridine was followed by immediate recovery. This result suggests that sulfanilamide should not be used in the treatment of infections due to Group B streptococci. Sulfapyridine is apparently an effective agent, and it is reasonable to hope that sulfathiazole and sulfadiazine may also be valuable therapeutic chemicals for use in these cases.

Group C

Group C hemolytic streptococci were isolated from the circulating blood of an old man with an aplastic anemia who developed chills and fever following a skin infection. Treatment with sulfadiazine resulted in prompt recovery, even though less than 500 granulocytes per cubic millimeter were demonstrable in his blood. He died several months later of inadequately treated colon bacillus bacteremia. This individual developed antistreptolysins and antifibrinolysins indistinguishable from those that are present in the blood following recovery from infections with Group A streptococci.

The striking results of treatment indicate that sulfadiazine is an exceedingly effective chemotherapeutic agent for use in infections due to Group C streptococci.

Group D

Group D hemolytic streptococci were recovered from the blood of an old man whose primary infection was in the kidney. Ten days before entry to the hospital he had developed chills and fever. Seven days later sulfapyridine was administered, followed by the development of complete anuria. The kidney pelves were lavaged for the purpose of dissolving the probable sulfapyridine calculi shortly after admission to the hospital. The urine obtained from the catheters contained innumerable cells and hemolytic Group D streptococci. Blood cultures obtained after the cystoscopy was completed, showed a growth of similar streptococci. No further sulfonamides were administered. The patient recovered uneventfully from the acute episode, but bacteriuria and pyuria persisted.

In summary, this was an example of Group D streptococcus pyelonephritis, complicated by the formation of sulfapyridine calculi and anuria. Bacteremia may have occurred as a result of instrumentation of the urinary passages.

Hemolytic and nonhemolytic Group D streptococci are well known. Together they constitute a division of the streptococci known as the enterococci, of which *Streptococcus faecalis* is the typical nonhemolytic variety. All these organisms are exceedingly resistant to the bacteriostatic action of the sulfonamides in vitro, and in a recent review of a large group of infections caused by them, it

was demonstrated that the sulfonamide drugs do not favorably affect the clinical course of Group D infections.⁵ Cases of nonhemolytic enterococcus bacteremia were presented in that report.

DISCUSSION

It has been well established that primary infection of the respiratory passages by hemolytic streptococci is nearly always caused by members of Lancefield Group A, but recent observations have demonstrated that these organisms are much less often the etiologic agents in infections of other organs. The frequency with which streptococci of the various groups may be isolated from the circulating blood of patients in whom infection is present may be used as an index of the severity of the disease processes caused by each. Previous studies show that hemolytic streptococci isolated from the blood in cases of scarlet fever, tonsillitis, otitis media and their complications will almost invariably be Group A strains, but that this will not be the case if the primary infection is located in the female genitalia, the skin, the kidney or the abdominal cavity.

Thirteen consecutive examples of hemolytic streptococcus bacteremia have been presented to emphasize these facts. No clinical data were available in 1 and terminal invasion of the blood occurred in 2. Three were cases of primary infection of the respiratory passages, and all were caused by Group A streptococci. The remaining 7 were examples of infection of the skin or kidney or were the result of surgical procedures. Strains of hemolytic streptococci of Groups B, C and D were the etiologic agents in 5 of these cases.

The results of sulfonamide therapy were of interest. Two Group A patients recovered and 2 died. The favorable effect of sulfadiazine in 1 case of Group A pneumonia and suppurative arthritis complicating chronic lymphatic leukemia was most remarkable. Two cases of Group B infection were treated with sulfapyridine. In one, postoperative meningitis appeared to be subsiding at the time therapy was instituted. In the other, a case of puerperal sepsis, sulfanilamide was without effect, but a change to sulfapyridine was followed by prompt recovery. One patient with Group C infection recovered after the exhibition of sulfadiazine, in spite of the presence of an aplastic anemia with agranulocytosis.

In a previous study,⁵ it was demonstrated that the drugs of the sulfonamide group were without effect in infections caused by Group D streptococci. Suggestive evidence is presented here that sulfanilamide may not be of value in serious Group B infections. It is apparent that the determination of the serologic group of a streptococcus recovered

from the blood or other clinical materials, particularly if the primary infectious process does not lie within the respiratory passages, is of definite importance. At the present time, sulfanilamide is the most widely used chemical for the treatment of hemolytic streptococcus infections, but may not be the drug of choice in certain cases. In others, the presence of Group D organisms may suggest that sulfonamides be withheld, or may explain their therapeutic failure.

The accumulation of further observations, similar to those described here, will also contribute to a more complete understanding of the nature, course and prognosis of serious disease caused by the less common groups of hemolytic streptococci

SUMMARY

Streptococci of Lancefield Group A were responsible for only 6 of 13 cases of hemolytic streptococcus bacteremia.

Organisms of Group A are almost invariably the cause of serious primary hemolytic streptococcus infections of the respiratory tract

Severe infections of other organs are frequently due to streptococci of other groups, particularly Groups B, C, D and G

The importance of serologic classification of the hemolytic streptococci in relation to certain aspects of sulfonamide therapy is discussed.

PHONOCARDIOGRAPHIC STUDIES IN A CASE OF PAROXYSMAL TACHYCARDIA

HENRY WEYLER, M.D.,* AND CECIL C DUSTIN, M.D.†

PROVIDENCE, RHODE ISLAND

CLINICAL descriptions of the heart sounds at the onset of paroxysmal auricular tachycardia are vague. They are usually described as sharper and louder than normal or as having a clicking quality. The phonocardiograms that are to be described in this paper are of particular interest because they show changes in sound at the onset of auricular tachycardia and present a clearer description of the events taking place.

In order to interpret phonocardiograms it is necessary to distinguish between the stethoscopic and logarithmic registration of sound. As pointed out by Rappaport,^{1,2} the stethoscopic method records sounds as they are presented to the ears of the observer by an average acoustic stethoscope, modified by the instrument but not modified by human hearing. Sounds of low frequency are best recorded by this method. The logarithmic method,

on the other hand, modifies the sounds of the heart exactly as does the combination of the average acoustic stethoscope plus average hearing. In the following description of phonocardiograms it is to be noted that comparative measurements of loudness will be made on the logarithmic tracings, the sounds being similar to those heard by a person with average hearing using the ordinary acoustic stethoscope.

In the case being presented the stethoscopic phonocardiograms (Fig 1) show during the normal heart beat a definite auricular sound, which occurs between the P and Q waves in the electrocardiogram. The first sound is distinct and commences with the R wave. The second sound starts at the end of the T wave. There is a third heart sound and evidence of a midsystolic murmur. When paroxysmal tachycardia sets in, the sounds change. The auricular sound gradually increases in intensity during the first few beats. The first sound, on the other hand, in most of the runs of tachycardia immediately shows a marked

*Assistant visiting physician, Rhode Island Hospital, assistant cardiologist Providence Lying in Hospital

†Visiting physician Rhode Island Hospital cardiologist Providence Lying in Hospital

increase in intensity and remains at about the same level throughout the tachycardia, becoming at times slightly higher after the first few beats.

increase in intensity with the onset of the tachycardia. At the same time the auricular sound gradually increases in intensity and duration, thus

FIGURE 1. Phonocardiograms by the Logarithmic and Stethoscopic Methods.

The upper record was made by the logarithmic method. It shows the end of a run of auricular tachycardia, followed by two slow beats, the first of which is considered normal for this patient. Note the absence of auricular sounds during the tachycardia.

The lower record was made by the stethoscopic method. It shows the onset of auricular tachycardia. There is a gradual increase in intensity of the auricular and first heart sounds. (Most of the runs of tachycardia in this patient showed a more abrupt increase in loudness of the first heart sound at the onset of tachycardia.) The auricular sounds in this case were below human audibility.

Both diastole and systole become shorter—diastole more so than systole. The second sound also becoming part of the first sound after the first, second, third or fourth beat.

FIGURE 2. Phonocardiograms and Jugular Tracings.

The upper record was made by the logarithmic method. It shows a run of tachycardia just after onset, followed by two slow beats. The jugular tracing shows a carotid effect. All sound tracings were made from the region of the apex of the heart.

The lower record was made by the stethoscopic method. It shows the abrupt onset of the tachycardia after two slow beats.

increases in intensity but not with the same increment as the first sound. It is to be pointed out again that the first sound attains a marked

Phonocardiograms registered by the logarithmic method during the normal slow beats show no auricular sound in most of the tracings. Occa-

sionally an auricular beat of very low intensity is seen. This indicates that the auricular sound recorded by the stethoscopic method is for the most

than it is during the normal slow beats. Because of variations in the normal heart sounds in this case, one cannot expect to find a constant ratio

FIGURE 3 Phonocardiograms and Apex Cardiograms (Linear Tracings)

The upper record was made by the logarithmic method, and the lower by the stethoscopic method. Vibrations consistent with a systolic murmur are present in both records. The stethoscopic phonocardiogram shows the end of a run of tachycardia and the onset of another run.

part below human audibility so that any increase in loudness of the first sound at the onset of tachycardia is not due to summation.

The first sound is distinct and commences with the R wave and is, in turn, followed by a decreascent systolic murmur. The second sound occurs at the end of the T wave. When the long pauses occur, the third heart sound is not present because it is below human audibility. When tachycardia sets in, there is an abrupt increase in intensity of the first sound with a slight increase in the second sound. Still, no auricular sound is recorded. There is a remarkable uniformity in the loudness of the first sound throughout the paroxysmal tachycardia. This also holds true for the second sound. In contrast, when the first sound of one normal slow beat is compared with the first sound of another normal slow beat there is considerable variation in loudness.

The second sound shows less variation in these records. Any changes in ratio between the intensity of the normal slow beat and the intensity of the tachycardia are due to variations in the loudness of the slow beat rather than to the more fixed loudness of the tachycardia. The first sound during tachycardia is from 2.1 to 4.5 times louder than it is during the normal slow beats. Similarly, the second sound is from 0.10 to 0.13 times louder

between the normal heart sounds and the abnormal sounds found in the tachycardia.

The phonocardiograms taken with the jugular cardiograms (Fig. 2) and the apex cardiograms or linear phonocardiograms (Fig. 3) corroborate the above findings.

SUMMARY

Phonocardiographic studies were made in a case of auricular tachycardia. Logarithmic phonocardiograms show an abrupt increase in intensity of the first sound, 2.1 to 4.5 times louder than the first sound in the normal slow beats. The second sound is only slightly increased in intensity, being 0.10 to 0.13 times louder than the normal slow beats. Stethoscopic registrations show a gradual increase in the auricular sound during the first few beats. In the case reported, the auricular sound is, for the most part, below human audibility.

These findings suggest that loudness of the first sound at the onset of tachycardia is not entirely due to summation.

CLINICAL NOTE

ADRENALIN BASE SUSPENDED IN AN AQUEOUS SOLUTION OF SODIUM THIOLYCOLATE IN THE TREATMENT OF ASTHMA*

CAPTAIN HYMAN L. NATERMAN, M.C., A.U.S.†
BOSTON

KEENEY¹ has shown that adrenalin base suspended in oil has a prolonged effect and is beneficial in the treatment of some cases of persistent asthma. My² experience with oil preparations has suggested that it was the insolubility of adrenalin base in tissue fluids rather than the use of oil as a vehicle that was responsible for their prolonged action. Moreover, repeated subcutaneous injections of oil cause induration in the skin. Therefore, a method of preparing stable suspensions of adrenalin base in water was sought. Adrenalin base suspended in water oxidizes rapidly. Although reducing agents prevent this oxidation, acid-reducing agents are not suitable because they convert the insoluble base adrenalin into the soluble acid salt. Accordingly, a reducing agent effective at a pH of 7.0 or higher is necessary; sodium thioglycolate meets these requirements. The method of preparation and the results observed in the treatment of 5 asthma patients with adrenalin base suspended in a solution of sodium thioglycolate in water are presented.

Adrenalin base‡ and suprarenin base§ were used. The most satisfactory method of preparation was to dissolve sodium thioglycolate|| in distilled water, and to neutralize this with disodium

phosphate. Glycerin and chlorbutanol were added. The final proportions were sodium thioglycolate 2 per cent, glycerin 10 per cent and chlorbutanol 0.5 per cent. The solution was sterilized by autoclaving or, preferably, by Berkefeld filtration. Adrenalin base was then added to make a suspension containing 2 to 4 mg. per cubic centimeter. The suspensions were bottled in sterile rubber-capped vials of 20 to 50 cc. Such suspensions frequently showed no evidence of oxidation for periods up to fifteen months, although in some lots changes in color suggestive of slight oxidation occurred. However, these slightly oxidized preparations lost no measurable amount of their potency.

Injections were self administered subcutaneously by the patients. After the vial had been shaken to disperse the adrenalin evenly, the required dose was taken out. The doses varied from 1 to 4 mg. Injections were given in some cases prophylactically to prevent attacks, and in others therapeutically to relieve attacks. They have been taken one to five times a day for periods as long as two years by the patients. The local reactions have been similar to those produced by adrenalin solution. General reactions have sometimes occurred, but usually three or more times the tolerated amount of soluble adrenalin may be given with no general adrenalin reaction. The intervals between attacks are prolonged and breathing is more nearly normal when adrenalin base suspended in water is used rather than adrenalin solution.

Adrenalin suspended in water seems to be as effective as, and in some cases more effective than, adrenalin suspended in oil. The easier administration and milder local reactions of adrenalin suspended in water are advantages over the oil preparation.

MEDICAL PROGRESS

ORTHOPEDIC SURGERY

GEORGE W. VAN GORDER, M.D.*

BOSTON

POLIOMYELITIS

ALTHOUGH the Kenny concept and treatment of infantile paralysis has been well described in a previous progress report by Watkins,¹ it is of sufficient importance to mention again, since it is one of the most outstanding advances in orthopedic surgery, as well as being a great contribution to the field of physical therapy. The usual conception that poliomyelitis produces simply flaccid paralysis is not tenable if one accepts the ideas of Sister Kenny, for she has proved that the major symptoms early in the disease are not so much flaccid paralysis as they are "muscular spasm," "inco-ordination" and "mental alienation."

The Kenny method of overcoming muscle spasm, tenderness and hyperirritability by means of the early application of hot packs instead of by immobilization in splints has done much to eliminate stiff joints, muscle contractures, spinal curvatures attributable to contractures and atrophy from disuse. Moreover, this new form of therapy followed by her system of muscle re-education has yielded functional results equal or superior to those of any other method.

FRACTURES AND DISLOCATIONS

Operative fixation of fractures of the clavicle by means of a Kirschner wire has been the subject of much discussion since Murray² wrote his original paper on the subject two years ago. In Murray's hands, these fractures seem to do extremely well, but the procedure requires considerable experience and the technic is more difficult than it appears to be from the author's description, which follows:

When a satisfactory reduction has been obtained a quarter inch [0.6 cm.] incision is made one inch [2.5 cm.] from the inner end of the clavicle. Through this, a hole, a quarter of an inch [0.6 cm.] in diameter, is drilled in the thin cortex. The direction of the drill is gradually changed from the perpendicular until it points toward the central cylinder. Through this hole a medium sized Kirschner wire is passed. If it is started in the right direction it always traverses the central cylinder and passes across the fracture line into the distal fragment, provided the reduction has been satisfactory. The clavicle immediately

becomes stable, and the arm, shoulder, and clavicle can be moved about quite freely without any displacement of the fragments. The wire is cut short and a small dressing is applied over the incision. If for some reason it is to be removed later on, this can be done through a very small incision under local anesthesia. No other fixation except a sling is required, and the patient is quite comfortable.

Several infections and one death are known to me to be the result of this method of treatment, and since open reduction is so seldom indicated in fractures of the clavicle, it seems questionable to adopt the procedure for routine use. However, in selected cases where conservative measures have failed, this method of Murray's can be employed with excellent results.

The same author recommends a similar procedure³ for acromioclavicular separations and uses two Kirschner transfixation wires in the acromion and outer third of the clavicle for immobilization. Phemister⁴ has modified this technic by advocating open reduction of the acromioclavicular joint and threaded wire fixation.

For fractures of the shaft of the humerus, Caldwell⁵ has proposed the hanging cast method of treatment, which in his hands has yielded very good results. A plaster cast is applied from the axilla to the base of the thumb with the elbow at right angles and the forearm in the position of midpronation. A wire loop is incorporated in the cast at the level of the wrist, and through this a bandage is passed that encircles the patient's neck. The hanging cast allows freedom of motion at the shoulder and is of sufficient weight in itself to afford any necessary traction. It is suitable for shaft fractures only; supracondylar and surgical neck fractures are not included in Caldwell's report. Since traction is the result of gravity in this method, it is important to warn the patient not to rest his cast on the arm of a chair or other support and to sleep at night with his body in the semiupright position.

As a general rule, the cast is retained for six weeks with gradually increasing motion as discomfort subsides. It is followed by a sling at 90° with light use of the arm and swinging exercises during the day. At the end of eight weeks all dressings can usually be removed, and at the end of

Reprints of articles in this series are not available for distribution but the articles will be published in book form. The current volume is *Medical Progress Annual Vol. III 1942* (Springfield Ill no. 5 Charles C. Thomas Company 1942 \$5.00).

*Instructor in orthopedic surgery, Harvard Medical School; chief orthopedic surgeon, Massachusetts General Hospital.

three months the patient should have full restoration of function.

A simple and effective method of treating fractures of the upper two thirds of the humerus has been reviewed by Gurd.⁶ The method is not new and has also been advocated by Eliason and others. It is included in this report because of its importance and need of re-emphasis.

Briefly, the treatment consists of placing a triangular pad under the axilla with a base which affords abduction of the arm of 15 degrees. The arm, shoulder and thorax are then incorporated in a plaster cast; the forearm is left free and is supported by a sling. The sling is removed in seven to ten days, and active motion of the elbow joint is begun. The cast is removed in two to five weeks; a cravat sling is supplied, and active use of the limb is advised. The method described has been used by the author for twenty years with satisfactory results, although no statistical study of end results has been made. It was not used for fractures of the anatomic neck or of the greater tuberosity of the humerus.

The treatment of fracture of the ulna associated with dislocation of the head of the radius (Monteggia fracture) has been greatly facilitated and improved by the work of Speed and Boyd,^{7,8} who have described an excellent surgical approach to this problem and related their experiences in a series of 62 cases. The subject is ably presented and should be read in full by any surgeon especially interested in this fracture.

Fractures of the carpal scaphoid are often mistaken for a sprained wrist because of their failure to show a fracture line in the initial x-ray film. Thorndike and Garrey⁹ in a college clinic saw 17 cases, 11 of which had old or previously unrecognized fractures. The failure to demonstrate these fractures by roentgenograms, especially in the initial examination, has been frequently mentioned. They suggest that better views may be taken with the fist clenched and the fingers resting on the x-ray plate with the palm down in extreme ulnar deviation and extreme pronation. If a true undetected fracture is present and motion is permitted, absorption of the bone occurs along the fracture line, and the fracture becomes more evident in one or two weeks. Treatment of these fractures has become standardized and was recorded in the last progress report on fractures.¹⁰

A practical suggestion to improve the treatment of a badly comminuted Colles's fracture, in which it is difficult or impossible to maintain radial length by the usual position of ulnar deviation, is to employ skeletal traction on the thumb. A plaster cast is first applied to the broken wrist in the orthodox manner for immobilization of a reduced Colles's fracture, after which a heavy wire such as is used for coat hangers is shaped to extend

5 to 7 cm. beyond the tip of the thumb with its two free ends anchored in the plaster cast. This wire acts as a framework to which traction can later be applied. A fine Kirschner wire is then drilled through the proximal phalanx of the thumb and cut to sufficient length to engage in the loops of a light wire stirrup, which just covers the thumb end. Traction on this stirrup by means of rubber bands attached to the extended wire frame draws the thumb distalward, increasing the degree of ulnar deviation and pulling on the radial collateral ligament, which in turn draws the styloid process of the radius distalward into the desired position and holds it there until union takes place.

The results of treating fractures of the neck of the femur by means of internal fixation, as advocated originally by Smith-Petersen, are more gratifying as time goes on. The percentage of unions and of excellent function is increasing with experience and improved technic. From a comprehensive study¹¹ of the results of internal fixation of fractures of the neck of the femur by the Fracture Committee of the American Academy of Orthopedic Surgeons, it was learned that the Smith-Petersen nail was more efficient than nails of other types, pins or wires in respect to maintaining reduction, incidence of breaking, migration and percentage of bony union obtained.

It has been pointed out recently by Wilson¹² and Carrell¹³ that fractures of the neck of the femur in children are much more serious injuries than in adults, and the results on the whole have been very disappointing. This is probably due to the fact that adequate immobilization of the fracture cannot be obtained by plaster-cast fixation alone and that internal fixation cannot be employed in children because of the danger of injuring the epiphyseal line and arresting growth. An ideal method of treatment is so far unknown. Carrell thinks that, after reduction fixation is best secured by abduction, plaster and traction.

Interest has been centered recently on intertrochanteric fractures of the femur, chiefly because of their high mortality rate. Leydig and Brooks¹⁴ report a series of 302 cases at the St. Louis City Hospital in which the mortality rate was 39.3 per cent. Moreover, a survey of seven of the large private hospitals in St. Louis revealed a mortality of 25 per cent in 335 cases, over twice that implied in the literature and textbooks. Although this high mortality rate has not been experienced by all investigators, it is apparent that the rate for intertrochanteric fractures is much higher than that for femoral-neck fractures (11.6 per cent). In view of this fact, Leydig and Brooks attempted to treat a series of intertrochanteric fractures by fixation with a Smith-Petersen nail, but found that the im-

mobilization was inadequate and that in every case there resulted *coxa vara* and shortening of various degrees. For this reason, they employed a lag bolt instead of the nail, and report their present results as satisfactory.

For similar reasons, Thornton¹ has designed a combination Smith-Petersen nail and bone plate that secures the intertrochanteric fragments in an admirable way, preventing *coxa vara* and allowing early convalescence as in fractures of the femoral neck.

The status of the Roger Anderson method of treating fractures varies in different parts of the country. I have seen very few end results of this method and have no accurate statistics to go by. The only series of cases known to me was reported in an address by Dr. Charles Bradford, of Boston, who recently returned from the American Hospital in England, where there were 61 selected cases that were treated by the Roger Anderson method. Of these, 30 were in the femur, 16 in the lower leg, 3 in the humerus, 6 in the forearm, 5 in a metacarpal and 1 in the mandible. According to Dr. Bradford

In the femur cases the alternative to using the Roger Anderson method was usually bone plating whereas in the tibia and fibula cases, the Roger Anderson method was considered to be excellent. For the humerus conservative treatment was considered advisable or bone plating, rather than the use of the Roger Anderson apparatus, and for forearm fractures the Roger Anderson apparatus was considered as being questionable in its value. For the mandible and metacarpal fractures, a miniature Roger Anderson apparatus had to be specially made.

Of the 61 cases treated, 43 were clean cases, 6 were potentially infected, and 12 were seriously infected. In the 43 clean cases treated by the Roger Anderson apparatus, there was no infection in the pin holes. The same can be said for the 6 potentially infected cases. Of the 12 seriously infected cases in 1 the pin tracks became grossly infected, in 7 the pin holes healed completely, and in 5 there were small draining sinuses.

As regards the end results of the 61 cases above mentioned, 3 had delayed union due to distraction of the bone fragments. Also it was noted that knee motion was limited frequently in fractures of the femur when the Roger Anderson appliance was employed, but not so much when used in the tibia and fibula fractures. After the application of the splint the patients were not supposed to put full weight upon their limbs but some did it anyway. In some cases, it was necessary to perform the reduction of the fracture in stages rather than all at one time.

Some of the drawbacks of the Roger Anderson method were the pin hole infections and of the one hundred and sixty pin holes concerned in these fractures a post-operative discharge was present in twenty. Also it was the feeling of the surgical staff that the method requires a special type of mechanically minded surgeon and unless the instrument is used properly it can give bad results. It is emphasized by those who have had experience with this treatment that the method is not an easy one and is really a hinder way to treat fractures

than by the usual standardized methods. Also when a comparative series of cases was treated at the Boston City Hospital at one time those treated by the Roger Anderson apparatus showed more delayed union than did those treated by the usual methods of skeletal traction or plaster casts.

Another serious disadvantage of the Roger Anderson method is that it requires a dangerous degree of exposure to x-rays, as has been demonstrated in clinics where the method is used.

On the other hand, when the Roger Anderson splint is applied properly in a successful case, the patient becomes ambulatory in a week or two so that, from the standpoint of evacuation of patients this method is an excellent one and especially applicable for war conditions.

The method of treating comminuted fractures of the patella by excision has spread into other fields of surgery, and one finds that complete removal of this bone is yielding favorable results in selected cases of arthritis, tuberculosis, chronic osteomyelitis, Pigeon's disease and traumatic osteochondritis.

An interesting and unusual fracture has recently been described by Hall.¹ It is located in one or more of the spinous processes of the lower cervical or upper dorsal vertebrae, and is called 'clay shoveler's fracture,' since it usually occurs in laborers while throwing up a shovel of clay. The clay sticks to the shovel, the worker feels a sudden stab of pain and sometimes hears a crack between the shoulders, and is unable to continue working. The symptoms are pain between the shoulders, nearly always on one side of the midline and sometimes beneath one scapula. It is made worse on forward stretching of the arms or on attempting to pull or lift anything. Sometimes the pain goes up to the head or down the spine, and in a few cases it proceeds down the arm, which invariably feels weak. Also, the patient may hear a click on performing certain movements. Examination reveals tenderness of the spinous processes at the site of fracture and tenderness along the course of the rhomboid muscles. Likewise, mobility of the affected spinous process can usually be detected. Flexion of the head invariably produces pain. The diagnosis is mistaken in the majority of cases for muscle strain. In Hall's opinion, the treatment indicated is removal of the detached fragments.

TUBERCULOSIS OF BONES AND JOINTS

Two new methods of treatment of tuberculosis of the hip are worthy of mention. One is known as femoroischial transplantation and the other as 'femoroischial fusion.'

The former method is described by Bosworth¹ and is usually employed when the head and neck of the femur have been totally destroyed. An

oblique osteotomy is performed just above the level of the ischial tuberosity, and the sharpened end of the divided femoral shaft is inserted into the tuberosity of the ischium, which is split and levered apart for this purpose. When sinuses exist, the operation may be performed in two stages, the first stage being the removal of the diseased trochanter, neck and remnants of the femoral head plus granulation tissue and so forth, in an effort to obtain complete closure of all wounds.

The femoroischial fusion method has been described by Trumble¹⁸ and consists of ankylosing the lesser trochanter area of the femur to the tuberosity of the ischium by means of a bone graft. This is actually a form of extra-articular arthrodesis, and after union of the graft takes place, the disease in the hip joint proceeds to subside and eventually to disappear. The advantage of this type of fusion is that the operative site is sufficiently distant from the area of disease to allow good healing. The surgical approach is posterior, and is the same as the standard approach to the sciatic nerve under the gluteus maximus by reflecting the muscle from its insertion. A strong tibial graft is used to bridge the space between the ischium and femoral shaft.

In fusion of knee joints and ankle joints, Hatt¹⁹ recommends the use of a central bone graft, which he has found to be successful and not associated with any unfortunate complications or retardation of growth, even though the graft passes completely through both epiphyseal lines adjacent to the articular surfaces. This type of fusion is especially applicable to children, in whom the danger of arrested growth is always imminent. Hatt employs two special bayonet-shaped instruments to facilitate his operative procedure.

BONE TUMORS

Two new types of bone tumor have been described recently—namely, osteoid-osteoma and eosinophilic granuloma.

The former was reported by Jaffe²⁰ in 1935, and since that time he and Lichtenstein have collected 33 cases. They describe the lesion as being always small and affecting the substantia spongiosa or cortex of a single bone. It is often mistaken for sclerosing or nonsuppurative osteomyelitis. Roentgenogram interpretation of this tumor is discussed in detail in their paper,²¹ and the authors believe that the condition is a benign neoplasm.

The second new bone tumor, eosinophilic granuloma, has also been reported by Lichtenstein and Jaffe.²² It occurs in young persons, especially boys and young men, and mainly involves the calvarium, but it may occur in other bones, such as the ribs, femur, vertebrae, humerus and pelvis, the flat bones appearing to predominate. Green,

Farber and McDermott²³ have very recently presented 10 additional cases. Farber²⁴ suggests that the lesion is a variant of the basic process of which Hand-Schüller-Christian and Letterer-Siwe diseases are other examples, and disagrees with Lichtenstein and Jaffe in considering the condition a distinct new entity.

Roentgen examination of this tumor shows localized lesions starting in the medullary cavity and expanding and eroding the cortex. Single lesions simulate bone cysts, osteomyelitis or malignancy, while multiple lesions suggest multiple myeloma. Histologically, the tumors are characterized by phagocytosed eosinophils, with giant cells also present. There may be an eosinophilia of the blood, and a sternal biopsy may show many eosinophilic cells. So far as is known at the present time, the tumor appears to be benign, and the lesions have healed promptly after roentgen radiation, curettage or wide excision.

Revived interest in the treatment of osteogenic sarcoma has been aroused by Ferguson,²⁵ who made a detailed statistical study of 400 cases reported in the Registry of Bone Sarcoma of the American College of Surgeons. As a result of this study, he recommends the following treatment for osteogenic sarcoma: avoidance of early amputation ("early amputation is defined as amputation before the seventh calendar month after onset of symptoms"); irradiation before delayed amputation; irradiation, excision and implantation of a bone graft or bone chips before amputation, with amputation before the recurrence becomes evident; and repetition of excision, rather than amputation, if recurrence becomes evident before amputation can be done.

The author's conclusions are so contrary to our previously accepted conceptions of treatment that it is difficult to accept them at first hand. The facts that he presents, however, must be recognized and studied carefully with an open mind.

HIP CONDITIONS

Congenital Dislocation

Scaglietti²⁶ reports that at the Rizzoli Institute in Bologna, Italy, this condition was diagnosed during the first year of life in 736 cases and the patients treated by abduction. Excellent results were obtained in 93.9 per cent, which shows the great importance of early diagnosis. The value of diagnosing dislocation of the hip during the early months of life cannot be too strongly emphasized, and as an aid to this end, Burman and Clark²⁷ have described minutely the outlines and markings evident in roentgenograms of infants between twenty-six days and twelve months of age, certain of which aid in making the diagnosis.

In those cases in which a Schanz osteotomy is thought to be advisable, Unger and Waring²⁸ maintain that it is essential to hyperextend as well as to abduct the distal fragment of the femur in order to compensate for the lumbar lordosis, and they describe a method by which the amount of hyperextension can be measured.

Traumatic Dislocation

In traumatic dislocation of the hip, it has now been learned that, following reduction, aseptic necrosis of the femoral head results much more frequently than was supposed and should be counteracted if possible by avoidance of early weight bearing. Too early weight bearing should never be allowed in these cases.

In a recent paper on this subject, Banks²⁹ reports 9 cases and discusses the problem of early diagnosis of aseptic necrosis of the femoral head. When ever possible, he suggests that the extremity be protected from weight bearing by means of crutches for four to six months after the postreduction period of immobilization or recumbency. During this period, he thinks that repeated x-ray examinations will probably show whether the femoral head is dead or alive, and that, dependent on this fact, weight bearing should be permitted or prevented until final revascularization and replacement by new bone have been completed.

Calvé-Legg-Perthes Disease

It appears from the experimental work of Compere, Garrison and Fahey³⁰ that multiple drilling of the neck and head of the femur for the purpose of revascularization in cases of Calvé-Legg-Perthes disease is a questionable procedure because of surgical trauma to the capital and greater trochanteric epiphyses, which results in arrest of growth, deformity, shortening of the neck of the femur, irregular contour of the femoral head and coxa vara.

The more recent articles that have appeared on this disease show a definite tendency toward agreement regarding treatment and prognosis. The treatment which ensures the best results is rest in bed with elimination of any weight bearing. Nearly all authors now agree that the major deformities, consisting of flattening of the head of the femur, bowing of the neck and deformation of the acetabulum, are the direct results of weight bearing stresses during the course of the disease, and emphasize the necessity for continuous freedom from weight bearing from first suspicion of the disease until the process is completed. This usually requires from two to three years.

Slipped Upper Femoral Epiphysis

This condition, if discovered early before displacement takes place, can be treated successfully by nailing through a lateral incision. The results are practically perfect. Early recognition is the key to successful treatment. When the condition is seen in the more advanced stage, with displacement and the line of junction still distinctly visible, the surgeon should then choose between an open reduction of the displacement, with nail fixation, and an osteotomy. Great care is essential in the preservation of the blood supply of the head and neck of the femur. Manipulation under anesthesia is to be condemned. In the late stages of this condition, osteotomy is considered by many to be the preferred procedure, but if not successful it should be followed by a cup arthroplasty.

Osteoarthritis

In the treatment of this common ailment, a variety of methods have previously been considered, such as manipulation, drilling, cheilectomy, osteotomy, acetabuloplasty, reconstruction procedures and arthrodesis. To this formidable list, another procedure offered by Smith Petersen³¹ can now be added, which will probably prove to be the most successful of all, namely, vitallium cup arthroplasty. This operation is standing the test of time and offers more hope of relief than any of the other procedures. It seems likely that vitallium cup arthroplasty and arthrodesis should be the two main procedures to choose between in the treatment of this condition, and that the decision should be made according to the individual patient's age, occupation and characteristics.

MISCELLANEOUS CONDITIONS

Torticollis

It appears from recent reports in the literature³² that division of both ends of the sternocleidomastoid muscle is a more efficient treatment for torticollis than severing only one end, and also does away with the necessity of postoperative retention apparatus, such as plaster casts or splints.

Intervertebral Disk

One of the serious objections to the use of iodized oil in myelography has been its possible irritating effects, and for this reason there has been a tendency to employ the less reliable procedure of pneumomyelography when making the diagnosis of ruptured intervertebral disk. Recently however, Kubik and Hampton³³ reported a simple method for the removal of the iodized oil from the subarachnoid space thus doing away with

any possible danger from its continued presence there. The oil is introduced by lumbar puncture with the patient on the fluoroscopic table, leaving the needle in place during the examination, and removing the oil immediately afterward. This improvement in diagnostic procedure represents a great advance in the attack on the problem of intervertebral-disk injuries.

The end results of treatment in 139 patients with protruded disks in the lumbar spine have been carefully analyzed by Barr and Mixter³⁴ who state that 77 per cent of the patients had complete relief from their radiating pain, and an additional 18 per cent had only minor discomfort in the affected leg; in other words, the relief from the sciatic pain was satisfactory in 95 per cent of the cases. About one third of the patients had their spines fused at the time of laminectomy, the other two thirds having laminectomy alone with removal of the protruding disk fragment. It is interesting and important to note that 73 per cent of the patients having fusion considered their backs of normal strength, whereas only 52 per cent of those without fusion had no complaints. Where insurance compensation was involved, it was found that after operation 45 per cent of the compensation patients went back to their original occupation and considered themselves fully recovered, 30 per cent went back to lighter jobs, and 25 per cent continued to receive compensation or had litigation pending. The fact that 75 per cent of these patients returned to some type of work is encouraging, and should justify co-operation from insurance companies in the attempt to rehabilitate otherwise totally incapacitated patients.

Scoliosis

Some very interesting and discouraging facts concerning idiopathic scoliosis have been brought to light by the Research Committee of the American Orthopaedic Association,³⁵ which reviewed 425 cases in sixteen orthopedic clinics from an end-result standpoint. The committee found that the disease appeared most frequently at the time of puberty, and predominated in girls in a ratio of 4:1. Curvature was to the right in 80 per cent of the patients. All types of treatment were encountered, but complete correction of the spinal curve was gained in only 5 per cent of the corrected cases, all the correction was maintained in 8 per cent, and there was complete loss of correction in 29 per cent. The incidence of pseudarthrosis for the entire operative group amounted to 28 per cent. The conclusions drawn from this very careful and illuminating study were as follows: practically none of the patients with scoliosis were cured, if correction of lateral deviation is a criterion; in approximately 60 per cent of those

treated by exercises the deformity increased, and in 40 per cent it remained unchanged; in the majority of cases correction without fusion resulted in complete loss of correction after support was discontinued; and correction by the turnbuckle jacket and subsequent fusion yielded better results than did other types of treatment.

Volkmann's Ischemic Contracture

The general impression is gaining that Volkmann's ischemic contracture should be considered to have a vasomotor origin. Numerous authors have emphasized this feature of the condition and have reported obliteration of the lumen of the brachial artery at the time of operative exploration. The removal of the tunica adventitia with its sympathetic fibers from the artery has resulted in the return of circulation in nearly all cases. Luzuy³⁶ reports two cases, and believes that in the absence of neural lesions the condition should be treated by injecting procaine hydrochloride into the stellate ganglion. Griffiths³⁷ thinks that the syndrome is due to injury of arteries and to accompanying spasm of the collateral circulation. He suggests the intravenous use of papaverine and adds that, if this fails, the contused or lacerated portion of the artery should be excised between ligatures. From the above and other recent reports, it would seem logical that a sympathetic block by novocain might be effective in removing the arterial spasm in many cases, and overcome the condition without resorting to radical surgery. This tendency to consider Volkmann's contracture an arterial spasm is undoubtedly a step in the right direction and advances knowledge regarding this very serious and crippling disorder.

Sulfonamides

The advent of the sulfonamides in the field of surgery has opened up possibilities beyond our imagination. Already we are taking advantage of their aid in overcoming wound infections and septicemia. War wounds have demonstrated their beneficial effects in a striking way, and surgical literature is full of data concerning the use of these drugs. It is not the function of this paper to discuss the relative merits of the different sulfonamide drugs in the treatment of compound fractures, osteomyelitis and war wounds, but only to state that, to date, it would appear that sulfanilamide is the substance of choice to introduce into open wounds as a bacteriostatic agent. In addition to this, one must always keep in mind the supreme importance of careful débridement and mechanical cleansing, the use of saline instead of iodine or alcohol as a cleansing solution, the value of plaster-of-Paris immobilization and the advantages of infrequent dressings.

MASSACHUSETTS MEDICAL SOCIETY

PROCEEDINGS OF THE COUNCIL

Stated Meeting, October 7, 1942

A STATED meeting of the Council of the Massachusetts Medical Society was called to order at 10:30 a m in John Ware Hall, 8 Fenway, Boston, on Wednesday, October 7, 1942, by the president, Dr. George Leonard Schadt, Hampden, 196 councilors were present (Appendix No. 1).

The records of the annual meeting held on May 25 and 26, 1942, as published in the June 25, 1942, issue of the *New England Journal of Medicine*, were presented by the Secretary.

The vice president, Dr. Perce H. Leavitt, moved their acceptance. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

REPORT OF EXECUTIVE COMMITTEE

This report (Appendix No. 2) was presented by the Secretary. He announced that the committee held two meetings during the summer, one a special session, held on July 10, and the other a regular meeting, held on August 26.

The meeting of July 10 was called by the president, Dr. George Leonard Schadt, in consequence

of a letter received from Dr. Frank H. Lahey, chairman of the Directing Board of the Procurement and Assignment Service. This letter was by way of an answer to a resolution offered by Dr. Reginald Fitz, state chairman of the Procurement and Assignment Service, and adopted by the Massachusetts Medical Society at its annual meeting on May 26, 1942. The Society, by this resolution, memorialized the Surgeon General, the Directing Board of the Procurement and Assignment Service and others for the purpose of making available for commissions in the medical corps of the armed forces a certain pool of physicians in Massachusetts who had been declared ineligible for such commissions. The committee recognized that the acceptance of the proposition submitted in Dr. Lahey's letter would involve the amending of the by-laws of the Massachusetts Medical Society. The committee further took notice of the fact that such an amendment could not be effective until passed on by the Society in May, 1943, a date much too late to be of use as a means of meeting what was then represented as an emergency.

The Secretary then spoke of the correspondence that followed with the Procurement and Assignment Service and the Office of the Surgeon General, which culminated in an agreement between the Massachusetts Medical Society and the office of the Surgeon General whereby the Surgeon General would include in the papers to be executed by the graduates of unapproved medical schools who applied for commissions in the Army the following form:

	Place	
	Date	
Dr.	of	

is known to this society as a graduate of Medical School, located in . . . He is engaged in the practice of medicine in Massachusetts, having been licensed by this state since . . . He is, so far as is known, an ethical practitioner of medicine. He would be eligible to apply for membership in the Massachusetts Medical Society if he had been in practice for five years. Having attained such membership, he would be accredited to the District Medical Society.

Signed _____, Secretary
District Medical Society

N.B. The applicant should bring his diploma and certificate of licensure to the district secretary.

The Secretary said that the Executive Committee had approved of this arrangement and moved that the Council do likewise. This motion was seconded by Dr. Charles J. Kickham, Norfolk, and it was so ordered by vote of the Council.

The Executive Committee, acting on the recommendation of the Committee on Membership, restored four former fellows to membership, denied the petition of one fellow to be so restored and allowed one fellow to change his membership from one district to another without changing his place of residence.

The report spoke in the highest terms of a report on state-aided cancer clinics by Dr. Channing C. Simmons, of Newton. The Council extended a rising vote of thanks to Dr. Simmons for his work in connection with this report.

The committee spoke of having reviewed the report of the Committee on Cancer, submitted by the chairman, Dr. Shields Warren, Suffolk. The committee approved the recommendations contained in this report.

The committee reviewed the report of the Committee on Public Relations, submitted by the secretary, Dr. Elmer S. Bagnall, Essex North. The committee approved the recommendation contained in this report.

The committee voted to lay on the table a letter from Mrs. John L. Bauer. This letter had been referred to the committee by the Council and

had to do with the formation in Massachusetts of a ladies' auxiliary to the American Medical Association.

Action on the petition of Dr. Frank R. Ober, Suffolk, past president, that two delegates be appointed to the annual meeting of the Associated State Postgraduate Committees was postponed.

The committee on the petition of Dr. Dwight O'Hara, Middlesex South, recommended the discontinuance of the Committee Appointed to Study the Practice of Medicine. The Secretary moved the adoption of this recommendation. The motion was seconded by a councilor, and it was so ordered by vote of the Council.

The committee, on the recommendation of Dr. Henry R. Viets, of Boston, recommended the discontinuance of the Committee on Army Medical Library and Museum. The Secretary moved the adoption of this recommendation; the motion was seconded, and it was so ordered by vote of the Council.

The committee voted to lay on the table the petition of Dr. Leroy E. Parkins, Suffolk, that the Council of the Massachusetts Medical Society request the American Medical Association to change the place of its annual meeting from San Francisco to some city in the Middle West.

The committee endorsed the work of the National Physicians Committee for the Extension of Medical Care and recommended that the Council of the Massachusetts Medical Society do likewise. The Secretary moved the adoption of this recommendation; the motion was seconded, and it was so ordered by vote of the Council.

The committee considered a plan offered by the Yankee Network intended to inform the public of the necessity of conserving doctors' time and energies during these times. The committee voted not to accept this plan.

The report spoke of a proposal of Dr. W. Richard Ohler, of Jamaica Plain, and others that the Massachusetts Medical Society enter in joint sponsorship with Harvard, Tufts and Boston University medical schools whereby postgraduate instruction might be provided for the medical officers of the Army and Navy on active duty within the confines of Massachusetts. The committee approves this proposal and recommends its adoption. The Secretary moved the adoption of the recommendations; the motion was seconded, and it was so ordered by vote of the Council.

The committee approved of certain ad-interim appointments made by the President.

The Secretary moved the adoption of the report as a whole. The motion was seconded by a councilor, and it was so ordered by vote of the Council.

REPORTS OF STANDING COMMITTEES

Arrangements (Dr. Gordon M. Morrison, Middlesex South, chairman)

This report (Appendix No. 3) was presented by Dr. Morrison.

He announced that the annual meeting will be held on May 17, 18 and 19, 1943, at the Hotel Kimball in Springfield. The annual meeting of the Council will be held on the evening of May 17.

Dr. Ralph R. Stratton, Middlesex East, moved the acceptance of the report. The motion was seconded by a councilor, and it was so ordered by vote of the Council.

Publications (Dr. Richard M. Smith, Suffolk, chairman)

No report.

Membership (Dr. Harlan F. Newton, Suffolk, chairman)

No report.

Finance (Dr. John Homans, Suffolk, chairman)

Dr. Homans said his committee was offering no formal report. He pointed out that, under the new by laws, chairmen of committees that will need funds to prosecute their work must prepare budgets that they must send to the Committee on Finance. The budget so presented must specify the purpose of all expenditures of \$100 or more.

He said that he had already sent out to the chairmen of the various committees a preliminary form, which would be of aid to them in reporting their proposed expenditures.

He pointed out that there was no provision in the by laws which made it mandatory for the officers of the Society to submit a budget. He added, however, that it was his opinion that there would not be much difficulty in this direction.

Dr. Carl Barse, Norfolk, moved the adoption of this report. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Ethics and Discipline (Dr. Ralph R. Stratton, Middlesex East, chairman)

No report.

Medical Education (Dr. Robert T. Monroe, Norfolk, chairman)

This report (Appendix No. 4) was offered as a preliminary report. A final report on the nursing situation produced by the War will be offered at the next meeting of the Council.

Dr. Monroe pointed out that the armed forces have asked for 60,000 registered, single nurses, forty five years or younger, who are in good physi-

cal condition. The committee believes that this demand can be met, pointing out, however, that this will create a shortage of nurses for civilian needs. The necessity of lowering the educational and training standards for graduate nurses, nevertheless, is not at hand. Future needs may possibly make such changes necessary.

The report mentioned the excellent work done by the Red Cross nurses' aides. A wider utilization of the attendant nurse was urged, and it was recommended that a campaign be begun at once to train large numbers of such nurses. The committee does not believe that such training should go on side by side with the training of the graduate nurse. The report further stated, however, that such an experiment is being tried at the Beverly Hospital.

Dr. Albert A. Horner, Suffolk, moved the adoption of the report. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Public Health (Dr. Francis P. Denny, Norfolk, chairman)

No report.

Medical Defense (Dr. Arthur W. Allen, Suffolk, chairman)

No report.

Society Headquarters (Dr. William H. Robey, Suffolk, chairman)

No report.

Industrial Health (Dr. Dwight O'Hara, Middlesex South, chairman)

This report was as follows:

Each of the committee's meetings has been attended by a representative of the State Department of Public Health and by the director of the Division of Occupational Hygiene of the State Department of Labor and Industries. Other meetings have also been honored by the presence of a member of the Council of Industrial Health of the American Medical Association, the president and secretary of the Massachusetts Medical Society and the state chairman of the Procurement and Assignment Service. The committee has also had the hearty co-operation of the editor of the *New England Journal of Medicine* and has made contact with the Associated Industries of Massachusetts.

With these reinforcements the committee has been able to visualize some of the problems now faced and about to be faced in industrial health in this state. An attempt has been and is being made to express these problems to the fellows of the Society by the publication of announcements and editorial comments in the pages of the *New England Journal of Medicine*. One of these editorials has been reprinted in full in *Industrial Medicine*, one of the nation wide manufacturers' publications.

This reinforcement of the committee also enabled it to secure, distribute and publicize to every doctor in Massachusetts a copy of the pamphlet, *Manual on Industrial Health for Defense*, prepared by the Massachusetts Committee on Public Safety.

On August 17 the committee voted that it "constitute itself as an agency to gather what information it can concerning doctors who may be available for industrial work and also information concerning possible placements for such doctors, working of course in co-operation with the Procurement and Assignment Service and with due regard for other than industrial need for medical service." Subsequently those doctors who indicated on their Procurement and Assignment blanks a primary interest in industrial practice have been invited to register with the committee. Of about 600 doctors, 260 had responded on October 4. The information thus obtained is being transferred to a punch-card system and will be available in case inquiries appear from industrial plants looking for medical service. To date there has been only one such inquiry, and it is likely that there is not as yet an acute shortage of industrial medical service. If such a shortage develops, however, or if the needs of industry rapidly expand in Massachusetts, the committee hopes to be in a position to be helpful.

The committee has also voted to hold a full-day "institute" on industrial health this fall and, with the help and co-operation of the Committee on Postgraduate Education, is preparing a program for Saturday, November 7, morning, afternoon and evening, at the Harvard Club of Boston. The committee is very much aware that no single program can cover the urgent matter in the field and is therefore hoping that the need and the interest may be sufficiently localized profitably to repeat or amplify this type of activity. Much more ambitious programs are under way in other parts of the Nation, and it may be that this method will prove itself a valuable one in the near future. At the moment, the committee is most perplexed to know how to reach the particular physicians who are most vitally concerned and strategically placed to make the largest contributions—those who are employed on part time or only casually in the small plants that are now rushing war production. Such plants employ three quarters of the labor in this state, but utilize an ever so much smaller fraction of the medical supervision that might be made available to them.

It was moved by Dr. Homans and seconded by a councilor that the report be accepted, and it was so ordered by vote of the Council.

REPORTS OF SPECIAL COMMITTEES

Public Relations (Dr. Elmer S. Bagnall, Essex North, secretary)

This report (Appendix No. 5) spoke of a conference which the committee had had with Mrs. Emma Tousant, chairman of the Industrial Accident Board. Out of that conference came the following recommendation by the committee:

Your committee recommends that the President be authorized to appoint a subcommittee (not necessarily limited to the membership of the Committee on Public

Relations) to confer with the newly appointed Medical Advisory Committee of the Industrial Accident Board to see what should be done and can be done to improve certain aspects of the medical administration of the Act, particularly those related to hospitalized cases.

Dr. Bagnall moved the adoption of the report. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Dr. Carl Bearse moved the adoption of the recommendation contained in the report of the Committee on Public Relations. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Tax-Supported Medical Care (Dr. Bagnall, chairman)

This report was as follows:

The Committee on Tax-Supported Medical Care has had no meetings since the last meeting of the Council. Matters are being referred by the Department of Public Welfare at the State House for consultation. These are being handled in some instances by reference to a special committee in the district concerned and decisions concerning policy are being satisfactorily arrived at.

This is the course the committee plans to follow pending developments that would indicate more active operations.

Dr. Bagnall moved the adoption of this report. The motion was seconded by a councilor, and it was so ordered by vote of the Council.

Postpayment Medical-Care Costs through Banks (Dr. Bagnall, chairman)

Dr. Bagnall stated that, since the last meeting of the Council, the Bankers Association has had a committee working on the further shaping of the plan for installment payments; when they are ready for action the committee will proceed jointly with them to commence operations.

Dr. Bagnall moved the adoption of this report. The motion was seconded by a councilor, and it was so ordered by vote of the Council.

Prepayment Medical-Care Costs Insurance (Dr. James C. McCann, Worcester, chairman)

Dr. McCann presented the report (Appendix No. 6). It was moved and seconded that the report be accepted, and it was so ordered by vote of the Council.

Procurement and Assignment (Dr. Reginald Fitz, Suffolk, chairman)

Dr. Fitz announced (Appendix No. 7) that one of the members of his committee, Dr. John J. Curley, Worcester North, had entered the Army, having been commissioned a major in the Medical Corps. He spoke of how valuable had been Ma-

for Curley's contribution to the work of this committee. He added that Dr Bartholomew P Sweeney, Worcester North, had taken Major Curley's place on the committee.

He spoke of the distribution of physicians in Massachusetts, as of the year 1941, and offered a table to supplement his remarks.

He said that the figures in the table suggested that the majority of members of the Society had filled out their enrollment forms. He added, however, that only 70 per cent of the 7713 doctors in the State had done so. He emphasized the need of the Army and Navy for young medical officers. He said that a random selection of 100 enrollment forms of physicians thirty-five years of age or younger showed that one third of them hoped to continue in private practice. Most of the latter group, however, were married and had dependents.

He expressed the thought that at this time there was no real medical depletion in the State. He said that this matter is being carefully watched and that machinery is at hand to prevent it or to cure it, if it arises.

He added that the medical problem of industry is beginning to assume a larger significance than heretofore. He added that his committee would soon be in a position to help industry find needed qualified doctors.

He said that the much debated question of the fate of graduates of substandard schools, licensed to practice medicine in Massachusetts, had been solved.

He believed that the work of the committee was progressing slowly but steadily along well-ordered lines. He spoke in a commendatory manner of the co-operation that the committee was receiving from the district committees, hospitals, medical schools and public health officials.

Dr Fitz moved the acceptance of the report. The motion was seconded, and it was so ordered by vote of the Council.

Survey of State Aided Cancer Clinics (Dr Channing C Simmons, of Newton)

The President announced that, inasmuch as each councilor had received in advance copy of this report (*New England Journal of Medicine*, issue of September 17, 1942, page 458), it was offered only by title.

Dr Shields Warren, Suffolk, moved its adoption. This motion was seconded, and it was so ordered by vote of the Council.

It was moved by Dr Hilbert F Day, Middlesex South, that a rising vote of thanks be extended to Dr Simmons in appreciation of his work. This motion was seconded by Dr Phippen, and on a standing vote, it was so ordered by the Council.

Cancer (Dr Shields Warren, Suffolk, chairman)

This report (*New England Journal of Medicine*, issue of September 17, 1942, page 462) made the following recommendations:

That the Council thank Dr Simmons for his services.

That it is advisable to suggest to the Department of Public Health the maintenance of existing clinics with the following exceptions: the state aided clinics at Quincy and at Newburyport should be discontinued.

That particular study be made of the clinics in Brockton, Greenfield, Pittsfield, Springfield and Hyanis to determine whether they can be more active and of greater service to their communities. (The physicians in these communities are now being interviewed to obtain their opinions of the clinics and their suggestions.)

Dr Warren moved the adoption of the recommendations. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Postgraduate Instruction (Dr Reginald Fitz, Suffolk, chairman)

The committee's report was as follows:

The committee voted unanimously to discontinue the usual extension courses and the New England Postgraduate Assembly during the current year.

The committee has assisted the Committee on Industrial Health in developing a postgraduate institute on industrial problems in medical practice, which will be given at the Harvard Club of Boston on Saturday, November 7. The program will be published in the *New England Journal of Medicine* next week, also it will be mailed to every physician in Massachusetts.

The committee will continue to study current needs for postgraduate instruction and will report progress at the next meeting of the Council.

Dr Fitz moved the acceptance of this report. The motion was seconded by a councilor, and it was so ordered by vote of the Council.

Physical Therapy (Dr Franklin P Lowry, Middlesex South, chairman)

No report.

Expert Testimony (Dr Frank R Ober, Suffolk, chairman)

Dr Ober offered a verbal preliminary report, in which he said:

We have had one meeting of the committee, at which all members were present, and it was voted that we obtain all possible information from the state societies in the country and the American Medical Association. I received a large package of material from the American Medical Association a few days ago, and I was told that it would have to be returned in six days. It is obviously impossible for the committee to absorb all the material in six days, and so I am having reprints sent from different organizations from which these publications came, and we hope to have a regular report for the February meeting of the Council.

Dr. Ober moved the adoption of the report. The motion was seconded by a councilor, and it was so ordered by vote of the Council.

Automobile Insurance Claims (Dr. Henry C. Marble, of Boston, chairman)

No report.

Convalescent Care (Dr. T. Duckett Jones, of Brookline, chairman)

No report.

Committee to Study the Practice of Medicine by Unregistered Persons (Dr. Richard Dutton, Middlesex East, chairman)

No report.

Committee to Meet with Massachusetts Hospital Association (Dr. Walter G. Phippen, Essex South, chairman)

Dr. Phippen reported as follows:

The committee appointed to confer with a committee from the Massachusetts Hospital Association had referred to it the following vote of the Council:

We believe that insurance cases (Blue Cross, Workmen's Compensation, automobile accidents and prepayment medical-costs insurance) should be submitted to hospitals in the care of their physician of choice. About half the hospitals of this state now provide this "private ward" privilege. The practice is almost universal outside the Atlantic Coast states. We recommend that the Council instruct the Committee to meet with the Massachusetts Hospital Association to see whether there can be agreement on a state-wide policy in this matter.

Dr. Charles Wilinsky, the president of the Massachusetts Hospital Association, was notified, and on August 12 a joint meeting of the two committees was held. There was free and open discussion by all members present. It was believed that there might rightly be considerable difference of opinion among hospitals and among the medical profession at large concerning the advisability of treating private patients in free wards of hospitals. It was thought, however, that since this type of service was apparently desired by members of the low-income group and since it could be paid for by various types of insurance it probably must be accepted. The hospital group stated very strongly, however, that in selling the Massachusetts Medical Service ward plan it must be made very clear that, unless the recipients are protected by a Blue Cross policy, they must assume the regular ward cost as determined by each individual hospital. It was also emphasized that the presence of a considerable number of private patients of many doctors in the wards of hospitals accredited for training of interns might materially interfere with this educational program.

Therefore, the following recommendations were adopted:

(1) Whenever possible, insurance cases (Workmen's Compensation, industrial accident, automobile accident, Blue Cross and Blue Shield) be segregated in special wards.

(2) Members of the Massachusetts Medical Service (Blue Shield) ward plan should be informed that they will be accepted to pay the prevailing ward rate to the hospital unless they have Blue Cross ward-plan insurance.

(3) Nothing in the operation of the Blue Shield plan shall interfere in any way with the standards of professional care established by the staffs and trustees of the various hospitals. This shall also include the standards set for the training of interns. Nor shall rules laid down by the hospitals for the admission of patients be altered under this plan.

(4) Nothing in the plans of prepaid insurance for medical care shall conflict with the existing policies of the various hospitals.

(5) The two committees strongly recommend that the hospitals throughout the Commonwealth co-operate with the Blue Shield, so far as possible.

Dr. Phippen moved the acceptance of the report. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Dr. Phippen moved the adoption of the recommendations contained in this report. The motion was seconded by Dr. Richardson, and it was so ordered by vote of the Council.

Committee to Examine WPA Records (Dr. Guy L. Richardson, Essex North, chairman)

Dr. Richardson offered the following report and moved its adoption:

A change in the method of handling the work of the committee has seemed advisable. The members of the committee were making regular visits to the WPA office to confer with Mr. Burns—state compensation officer. Because of the marked and continued decrease in the number of WPA employees and the consequent reduction in accident cases, together with the many added duties of all of us as physicians, a letter was sent to Mr. Burns advising him that we should not confer regularly at his office but should keep the contact by correspondence, and be available for conference when any matter came up which could not be settled properly by letter or telephone.

To quote from Mr. Burns's reply to our letter, which he dated September 2, the last two paragraphs may be of interest:

Strictly speaking, the Division has been markedly free of any controversial matter, and the volume of work has decreased to practically nothing. In making up this month's report I find that only 203 cases were registered for the month of August. I well recall the time when this would represent a single day's receipt.

Of course, we have less than 18,000 employed all over the State, which is only about 13 per cent of our former personnel. Indeed, if I have any problem, I shall seek your assistance without delay. Thank you for all the splendid co-operation given our organization by the Massachusetts Medical Society.

The motion was seconded, and it was so ordered by vote of the Council.

Maternal Welfare (Dr Judson A. Smith, of Newton, chairman)

No report

Rehabilitation (Dr William E. Browne, Suffolk, chairman)

Dr Browne reported (Appendix No 8) that his committee had in every way co-operated with the Massachusetts Selective Service Headquarters. He said that it seemed improbable that the federal government will, in the near future, undertake any extensive program of rehabilitation. When and if the Government does enter into such a program, the Massachusetts Medical Society, through this committee, will be ready to co-operate in an efficient manner.

Dr Browne moved the acceptance of the report. The motion was seconded by a counselor, and it was so ordered by vote of the Council.

Committee to Aid the Boston Medical Library (Dr William H. Robey, Suffolk, chairman)

Dr Robey said the committee had nothing definite to report.

APPOINTMENTS

The president offered the following appointments:

AUDITING COMMITTEE

Dr Francis C. Hall, of Brookline, chairman
Dr Burton E. Hamilton, of Brookline

COUNCIL

Dr George L. Gabler, Hampden, replacing Dr Stanley C. Cox, deceased
Dr G. Colket Caner, Suffolk, replacing Dr Roger I. Lee, who has become a member *ex officio*
Dr Merrill C. Sosman, Suffolk, replacing Dr Marshall N. Fulton, resigned
Dr John F. Casey and Dr Madelaine R. Brown, Middlesex South, replacing Dr Dwight O'Hara and Dr Eliot Hubbard, Jr., who have become members *ex officio*
Dr Sumner H. Remick, Middlesex South, replacing Dr Roy D. Halloran, resigned
Dr George A. Buckley, Plymouth, replacing Dr Peirce H. Leavitt, who has become a member *ex officio*
Dr Herman D. Bone, Worcester North, replacing Dr John J. Curley, resigned
Dr Herbert Coulson, Essex North, replacing Dr David W. Wallwork, resigned

BOARDS OF CENSORS

Dr Andrew J. Leddy and Dr William M. Stobbs, Bristol North, replacing Dr William H. Bennett and Dr Curtis B. Kingsbury, resigned
Dr William W. Ferrin, Essex North, replacing Dr Arnold P. George, resigned

COMMITTEE ON EXPERT TESTIMONY

Dr Frank R. Ober, chairman, replacing Dr George Leonard Schadt, resigned
Dr William J. Brickley, replacing Dr James J. Goodwin, resigned

COMMITTEE ON ARRANGEMENTS

Dr Gordon M. Morrison, chairman (already a member)
Dr Sidney C. Wiggan, Dr Robert H. Barker and Dr Richard I. Smith, replacing Dr James A. Halsted (chairman), Dr George P. Sturgis and Dr Henry H. Faxon, resigned

COMMITTEE ON REHABILITATION

Dr John Fallon, replacing Dr David C. Dow, deceased

VOTING MEMBERS IN MASSACHUSETTS HOSPITAL SERVICE, INC.

Dr Donald Munro, replacing Dr Richard P. Stetson, resigned
Dr Ralph R. Stratton, replacing Dr James A. Halsted, resigned

COMMITTEE ON MEDICAL DEFENSE

Dr Ira M. Dixon, replacing Dr George S. Reynolds, resigned

COMMITTEE TO MEET WITH MASSACHUSETTS HOSPITAL ASSOCIATION

Dr Edward A. Adams, replacing Dr Reynolds, resigned

COMMITTEE TO AID THE BOSTON MEDICAL LIBRARY

Dr William H. Robey, chairman
Dr Charles S. Butler
Dr David Cheever
Dr Michael A. Tighe
Dr Shields Warren

COMMITTEE TO MEET WITH THE ADVISORY COMMITTEE OF PHYSICIANS APPOINTED BY THE INDUSTRIAL ACCIDENT BOARD

Dr Daniel J. Ellison, chairman
Dr Gordon M. Morrison
Dr David D. Scannell

COMMITTEE TO WORK OUT THE NECESSARY ARRANGEMENTS FOR POSTGRADUATE WORK FOR THE ARMY AND NAVY

Dr W. Richard Ohler, chairman
Dr Chester S. Keefer
Dr Samuel H. Proger
Dr Lloyd E. Parkins
Dr Frank R. Ober

Dr Albert A. Hornor, Suffolk, moved confirmation of these appointments. This motion was seconded by Dr Homans, and it was so ordered by vote of the Council.

MISCELLANEOUS BUSINESS

The President announced that two members of the Council had died since the last meeting.

Dr. Stanley C. Cox, of Holyoke, died June 7, 1942, in his sixtieth year.

Born in South Hadley Falls, he received his degree from University of Michigan Medical School in 1910. For twenty-one years, he served as associate medical examiner and medical examiner for the third district of Hampden County. He was head of the local medical division of the Massachusetts Committee on Public Safety in Holyoke. He was a member of the American College of Surgeons, and a fellow of the American Medical Association.

Dr. Cox is survived by his widow, two sons and three daughters.

Dr. David C. Dow, of Cambridge, died May 27, 1942, in his sixty-eighth year.

Born in Cambridge, he received his degree from Tufts College Medical School in 1898. He was an intern at the Cambridge Hospital, where he was a member of the staff until his retirement a year ago. He was medical examiner of the First District of Middlesex County, and was a member of the American Medical Association.

Dr. Dow is survived by his widow, a son and a daughter.

At the request of the President, the Council stood in silence for one minute in tribute to the memory of Dr. Cox and Dr. Dow.

Dr. Bagnall, as a preliminary to offering a motion, said that he was a little bit concerned about the organization of the medical profession and the instruction of the public to meet the approaching shortage of doctors. He said that in Haverhill all men under forty-five years, except one, have volunteered for service. He added that this naturally placed a very much greater burden on the older men. He said that if the standards of medical care were to be maintained, it was necessary that the public be educated to conserve doctors' energies.

Dr. Bagnall then moved that the President be authorized to appoint a committee, the number of the committee to be at his discretion, to look into this subject for report to the Council at a later meeting. This motion was seconded by Dr. Fitz, and it was so ordered by vote of the Council.

Dr. James C. McCann, Worcester, was at this point recognized by the chair. He asked the councilors present to do what they could to stimulate their associates to sign the contract submitted by the Blue Shield. He added that these signed contracts were coming in at the rate of about one hundred each day; in all, about one thousand had been received.

Dr. Hornor asked the following question: "Why should an internist sign this contract?"

Dr. McCann replied as follows:

That, of course, is always an important point because internists will not come fully into the program until we have a more complete contract available for the

public. But the reasons for signing are two. For the most part, this contract goes down through the specialties. It does overlap into x-ray; it overlaps into the general man's work who is doing any orthopedics or obstetrics or any anesthesia. Those are the principal things covered. It also overlaps, but to a very minor degree, in the field of the man who is doing a medical consultation practice. Now, those are reasons forming one basis for considering participation. The other basis is that, since the Society at large has undertaken this thing as the Massachusetts Medical Society's corporation and has presented it to the public from that angle, the mere endorsement of it by a large segment of the profession, including the internists, will mean a great deal toward success. The Society has about 5700 members, and if a large proportion were to sign their contracts it would strengthen the initial step and lead to inevitable success, and we should be able to say to the public that we had a broad participation in it by the physicians of the State. Those are the only reasons I know.

At this point in the meeting, Dr. Peirce H. Leavitt, vice-president, assumed the chair and Dr. Schadt addressed the Council for the purpose of backing up everything Dr. McCann had said in answering Dr. Hornor's question. Dr. Schadt urged everybody to sign up so as to give emphasis to the fact that the Blue Shield is backed by the Massachusetts Medical Society.

Dr. Schadt returned to the chair.

Dr. Leavitt moved that local committees on membership be advised and urged to investigate carefully and examine all candidates in regard to their ethics and methods of practice. This motion was seconded by Dr. Walter H. Pulsifer, Plymouth, and it was so ordered by vote of the Council.

At 12:30 p.m., Dr. Carl Bearse, Norfolk, moved that the meeting adjourn. This motion was seconded by Dr. Harry F. Byrnes, Hampden, and it was so ordered by vote of the Council.

MICHAEL A. TIGHE, *Secretary*

APPENDIX NO 2

REPORT OF THE EXECUTIVE COMMITTEE

The Executive Committee held two meetings during the summer, a special meeting on July 10, 1942, and a regular meeting on August 26, 1942.

The special meeting was called by the president Dr George Leonard Schadt, in consequence of a letter which he had received from Dr Frank H. Lahey, chairman of the Directing Board of the Procurement and Assignment Service. This letter was by way of answer to the resolution offered by Dr Reginald Fitz and adopted May 26, 1942, by the Massachusetts Medical Society at its annual meeting.

The Council will remember that those who had to do with supplying medical officers for the armed forces were greatly troubled by the fact that there was in this state a very considerable pool of licensed doctors who by reason of their school affiliations were ineligible for commissions in the medical corps of the armed forces.

The Massachusetts Medical Society, in adopting Dr Fitz's resolution, memorialized the Surgeon General of the Army, the Directing Board of the Procurement and Assignment Service and others for the purpose of having the above ruling modified so as to make the members of this pool eligible for commissions under certain circumstances, which circumstances were set forth in the resolution.

We received acknowledgment of the receipt of this resolution from the Procurement and Assignment Service and from Surgeon General Magee. The Surgeon General's reply was received on June 15, 1942. In this letter he set forth four conditions under which the doctors in question would be accepted as applicants for commissions in the Medical Corps of the Army. One of these circumstances involved membership in the Massachusetts Medical Society. As these men had not been in practice for the necessary five years and consequently were not eligible

to apply for membership in our organization, the Surgeon General's letter did not solve the problem.

Dr. Lahey's letter, the reason for this special meeting, submitted a proposition in which the Surgeon General was reported to have concurred. This proposition involved an amendment to our by-laws. The Executive Committee, while expressing its every desire to be of service, felt that the acceptance of the proposition submitted involved the lowering of the standards of the Massachusetts Medical Society and that, furthermore, such a sacrifice would be without purpose inasmuch as any amendment to our by-laws could be ratified only at our annual meeting in May, 1943—certainly a too distant date to be of use in meeting what was at that time represented as an emergency.

Dr. Lahey was acquainted with the viewpoint of the Executive Committee.

On July 22, 1942, our office was in receipt of a letter from Dr. Lahey in which he enclosed a photostatic copy of a letter which he had received from Lt. Col. Lull, assistant to the Surgeon General. Colonel Lull's letter indicated that the Executive Committee's acts at its special meeting had come to the Surgeon General's attention. I will quote two paragraphs from this letter which refer to graduates of a certain medical school not on the approved list.

If these physicians meet the other qualifications, and have been practicing *less than five years*, the Surgeon General will accept a statement from the secretary of the county or district society to the effect that they are engaged in the ethical practice of medicine, and would be eligible for membership in the Society, except for the fact that they have been in practice less than five years.

The physicians who have been in practice for over five years, and who are not members of their district societies, will be denied commissions.

The President and Secretary, being satisfied that they understood the feeling of the Executive Committee in this matter, were somewhat troubled by the language which reads "and would be eligible for membership in the Society, except for the fact that they have been in practice less than five years." We suggested to the Surgeon General that this language be changed so as to read, "... be eligible to apply for membership in the Society. . . ."

The significance of such a change was not apparent to the Surgeon General, and there was further correspondence. This finally took the form of a statement from us to him as to how we felt we might be of help in this matter. We enclosed a form which we would direct the district secretaries to execute when presented by the applicant for a commission. Lt. Col. Lull suggested one very slight change in the form. This change has been made. The final form agreed upon is now on the screen [see page 744]. This form will be made part of the papers which the graduate of an unapproved school must have executed when applying for a commission in the Medical Corps of the United States Army.

As time was of the essence in this matter, a letter enclosing a copy of the form has already been sent to each district secretary asking him to evaluate the applicant from the standpoint of the circumstances outlined in the form. This is not a very great chore in the ordinary sized districts. In the larger ones, it may be necessary to set up some simple machinery to aid the secretary in arriving at the proper conclusion with regard to the individual applicant. The method, we are sure, may be safely left in the individual district.

No report on this matter would be complete without acknowledging the help received from Dr. Lahey, Dr. Fitz and Lt. Col. Marble. The Executive Committee hereby acknowledges with thanks that help. In the name of the Massachusetts Medical Society we have written the Surgeon General thanking him for this opportunity to serve.

The Executive Committee has approved of the method pursued and the conclusion arrived at in this matter.

The Executive Committee, acting on the recommendations of the Committee on Membership, has

- (1) Restored the following physicians to membership provided all their obligations to the Society are discharged within one month:

Gaspard M. Garoyan, Belmont
Lt. Col. Frank E. Lewis, Nantucket
Hugh B. Roney, Pittsfield
H. Sinclair Tait, Palmer

- (2) Denied the request of Dr. John F. McDonald that he be restored to membership.
- (3) Permitted Dr. Albert B. Ferguson to change his membership from Norfolk to Plymouth without changing his place of residence.

The Executive Committee was greatly impressed by the excellence of the report offered by Dr. Channing Simmons in the matter of his survey of the state-aided cancer clinics. This report has been sent to each councilor, together with the report of the Committee on Cancer, Dr. Shields Warren, chairman. The recommendations contained in this latter report were approved by the committee.

The Executive Committee reviewed the report of the Committee on Public Relations, Dr. Elmer S. Bagnall, secretary, and approved of the recommendation contained therein.

The committee reviewed the report of the Committee Appointed to Confer with the Massachusetts Hospital Association, Dr. Walter G. Phippen, chairman. The committee approves of the recommendations contained therein.

A letter from Mrs. John L. Bauer, presented to the Council at its annual meeting and referred to the Executive Committee, was laid on the table. This letter had to do with the formation in Massachusetts of a ladies' auxiliary to the American Medical Association.

Action on the suggestion of Dr. Frank R. Ober that two delegates be appointed to the annual meeting of the Associated State Postgraduate Committees was postponed.

The committee was in receipt of a letter from Dr. Dwight O'Hara, chairman of the Committee Appointed to Study the Practice of Medicine, asking for the discontinuance of this committee. The Executive Committee so recommends.

A letter was received from Dr. Henry R. Viets requesting that the Committee on Army Medical Library and Museum be discontinued. The Executive Committee so recommended.

Dr. Leroy E. Parkins suggested by letter that the Council of the Massachusetts Medical Society request the American Medical Association to change the place of its annual meeting from San Francisco to some city in the Middle West. The committee voted to lay this communication on the table.

The Executive Committee took notice of a resolution adopted at Atlantic City, June, 1942, by the House of Delegates of the American Medical Association, endorsing the work of the National Physicians Committee for the Extension of Medical Care. The Executive Committee voted to endorse the work of this committee and to recom-

ment that the Council of the Massachusetts Medical Society do likewise

The Executive Committee was aware that the calling of many doctors into the armed service was putting a severe strain on the time and efforts of those remaining at home

A summary of a plan intended to inform the public of the necessity of conserving doctors' time and energies was offered by the Yankee Network. The committee, having in mind the dwindling income of the Society consequent of the war, voted to decline the acceptance of this plan

Dr W Richard Ohler and others proposed that the Massachusetts Medical Society, in co-operation with Harvard, Tufts and Boston University Medical schools, sponsor a program of postgraduate instruction for the medical officers of the Army and Navy on active duty within the confines of Massachusetts. Preliminary conversations indicated that the schools, the Army and Navy were willing to participate in such a program

The committee voted to recommend to the Council that the Massachusetts Medical Society enter into such a program and that the President be authorized to appoint a committee of five to represent the Society in such joint sponsorship

Certain ad interim appointments, which will be offered by the President later in the meeting, were approved by the Executive Committee.

MICHAEL A TIGHE *Secretary*

APPENDIX NO 3

REPORT OF THE COMMITTEE ON ARRANGEMENTS

After a conference with the president and secretary of the Society, the Committee on Arrangements held a meeting at which it was decided to hold the next annual meeting on Tuesday and Wednesday, May 18 and 19, 1943, with the annual meeting of the Council on the evening of May 17. The Council, at its meeting last May, chose the meeting place as Springfield

Your committee anticipates that the 1943 meeting of the Society will be smaller in numbers and in exhibits than for the past few years, owing to gasoline rationing, to the fact that so many of our members have joined the armed forces and to other wartime conditions. For this reason we believe that the entire meeting can and should be held in the Hotel Kimball rather than in the Municipal Auditorium as it was the last time we visited Springfield

GORDON M MORRISON, *Chairman*

APPENDIX NO 4

REPORT OF THE COMMITTEE ON MEDICAL EDUCATION

At the request of the Executive Committee on June 24, 1942, we have investigated the nursing situation which has been produced by the war. We have consulted material from the American Nurses' Association and the hospital reports of the American Medical Association, and we have had conferences and correspondence with several hospital and nursing school executives and with the Army Nurses' Corps. These data impress us as requiring further study. The problem is complicated. It seemed best to ask your permission to accept a preliminary report today and to render a final statement at the next meeting

The sense of the following conclusions has been accepted unanimously by the committee

(1) The armed forces have asked for 60,000 registered graduate nurses, single, under forty five years of age and in good physical condition. Figures show that this need can be met, for in 1941 a national nurses inventory found 75,000 to 80,000 qualified women, and nursing schools will graduate 15,000 to 20,000 more this year. However, Army authorities have stated that they have had difficulty in getting nurses to sign up. We recommend, therefore, the closest possible co-operation between the Army Nurses Corps and the hospital executives and nursing school executives with a view to impressing on nurses who are qualified that it is their duty to join. It may be advisable to establish a nurses' procurement and assignment office to allocate them fairly. Perhaps the Army might be persuaded to accept certain married nurses, for marriage has not been a bar to the WAACs and WAVES

(2) The loss of so many nurses to the armed forces will create a serious shortage of nurses available for civilian needs. It has already done so. However, it is our considered judgment that at the present time there is no necessity for lowering the educational and training standards for graduate nurses, to speed up production. If the emergency increases, the possibility of some modification should be entertained. This would require changes in legislation in nursing registration regarding each of the forty-eight states

(3) Auxiliary nurses can be developed to meet the present situation. The Red Cross nurses' aides are important. They are for the most part mature women, they are taught quickly, and they have rendered excellent services already. Some five hundred centers are training them throughout the country. Perhaps 20,000 of the hoped for 100,000 have received certificates. The program is heartily endorsed. Other less voluntary services should be explored. For example, inactive graduate nurses who cannot return to full duty might be given part time work

(4) The attendant nurse is worthy of far more consideration than she has received. Her course is only twelve to eighteen months long, and her educational requirements are not so great as those for the graduate nurse. Yet she is trained to do the jobs which are not emphasized in regular schools or for which the graduate nurse usually shows little aptitude—namely, the care of patients in their homes and the care of chronic illness. Therefore she is just the nurse to be relied on for rapid development and for tasks imposed by civilian disaster. It is recommended that the American Nurses' Association, hospital executives and physicians recognize her value explicitly and do all in their power to raise her morale. It is also desirable that government agencies utilize her wherever possible, as in veterans' hospitals and other chronic hospitals for chronic diseases

A campaign should be begun at once to train large numbers of attendant nurses. This can be done without delay and with little cost if applicants can be attracted. The Household Nursing Association is running at only about 50 per cent of its capacity, it could double its capacity by using its eight affiliated hospitals more fully. There are 7 other attendant nursing schools in this state. More could be established if all the accredited small hospitals were engaged

It has been suggested that attendant nursing schools be formed in large hospitals alongside their regular nursing schools. This suggestion is opposed by the great majority of nursing educators and hospital administrators, and by

attendant nursing educators themselves. We believe that the experiment is not necessary and is not feasible because the two types of training are so different in objectives and in material required. Nevertheless it is being tried at the Beverly Hospital at the request of Mr. Frederick Ayer. The results will be instructive.

ROBERT T. MONROE, *Chairman*

APPENDIX NO. 5

REPORT OF THE COMMITTEE ON PUBLIC RELATIONS

The Committee on Public Relations has had a conference with Mrs. Emma Tousant, chairman of the Industrial Accident Board, concerning hospitalized beneficiaries of the Act. Mrs. Tousant believes that too often these patients do not get early and adequate care. She has conferred with insurance representatives, and they favor a gentleman's agreement to take care of the situation, rather than new legislation.

Preliminary discussion makes it apparent that there are problems that might be corrected by a meeting of minds. Your committee recommends that the President be authorized to appoint a subcommittee (not necessarily limited to the membership of the Committee on Public Relations) to confer with the newly appointed Medical Advisory Committee of the Industrial Accident Board, to see what should and can be done to improve certain aspects of the medical administration of the Act, particularly those related to hospitalized cases.

E. S. BAGNALL, *Secretary*

APPENDIX NO. 6

REPORT OF THE COMMITTEE CONCERNED WITH PREPAYMENT MEDICAL-CARE COSTS INSURANCE

The present opportunity is taken to make a report of progress concerning Massachusetts Medical Service. I should like to establish at this time the precedent of the president of the corporation making periodic reports to the Council on the progress of the Service. There are, furthermore, two other points at which intimate contact may be maintained between the profession and the corporation—first, the president can keep in touch with the districts by periodic meetings with the chairmen of the local professional-service committees and, second, the five physician members of the Board of Directors can sit at intervals with the members of the corporation (the Executive Committee of the Council) and thus be kept alert to the reactions of the physicians of the State. The maintenance of these close contacts will serve to maintain a proper understanding between the various groups involved in this venture.

It might be of interest to you to learn the fate of the resolution adopted by this group at its annual meeting relative to the principle of medical-service contracts. The resolution was presented and ably carried to the House of Delegates of the American Medical Association by your delegates, being presented on the floor by Dr. Mongan. With some slight change of wording it was adopted by the House of Delegates. Favorable comment on this action has appeared several times during the past few months in national publications interested in such problems.

It would be well at this time to take note of our indebtedness and express our appreciation to the lay members of the Board of Directors. Through the summer

months they have met several times in an effort to bring this endeavor to culmination. We are also indebted to the physicians who sat in the various committees which completed the necessary actions required to start the program. Particularly should we express our indebtedness to Dr. Nye and his associates on the staff of the *New England Journal of Medicine* for their whole-hearted co-operation in carrying information on the development of the program to the profession during the summer.

Very briefly I now report to you the actions that have been taken as a result of the several recommendations adopted by you on February 4, 1942. With reference to two recommendations,—one establishing the income levels of eligibility for service contracts as contrasted to indemnity contracts, and the other establishing the principle of developing a complete medical-care program through partial coverage contracts,—the Board of Directors voted approval of both these basic principles. With regard to the privilege asked to hire the services of an actuary, we did not find such a step necessary. Ample advice and help was forthcoming from Mr. Cleary, the actuary in the State Department of Insurance. The supplementary recommendation that empowered the Committee on Public Relations, the Executive Committee of the Council and additional appointees to review and establish the fee schedule and contracts was carried out by a summer meeting of this group. Two other recommendations—the first with reference to the selection of a director and the second relating to the establishment of a fund of \$25,000 by the Society—have been acted on. It is the opinion of the corporation that the financial requirements established by the Department of Insurance render it inadvisable at this time to employ full-time salaried agents. For the present, medical matters should be handled by voluntary committees of the Society. Business and administrative matters must be handled on a contract basis through the offices and agents of the Blue Cross. The financial requirements established by the Department of Insurance make no other course possible. What the future holds, so far as the relation of the two corporations is concerned, must evolve on the basis of experience. The remaining recommendation relates to the contractual relation between the Blue Cross and Massachusetts Medical Service. A carefully drawn contract supervised by the Department of Insurance safeguards the independent identity of the two corporations, and establishes the basis for the distribution of costs between the two corporations. It provides for the issuance of each corporation's contracts separately as well as jointly. The contract is renewable yearly.

It might prove of interest to you to have a brief report of the meetings that have carried this program into effect. As you will recall, prior to the annual meeting of the Society last spring, the Board of Directors of the corporation met and completed all necessary papers required to procure a charter. The charter was granted at the time of the annual meeting. At a subsequent meeting of the Board, in June, officers were elected, committees established, and approval voted of the general program as outlined by the Society. In July the Executive Committee of the corporation met with the actuary of the Department of Insurance, and the whole problem of the premium structure was thoroughly studied and decisions made. In August all basic contracts were studied by the Board and prepared for submission to the Department of Insurance. Following this, there were lengthy discussions with the representatives of the Department of Insurance, as a result of which the contracts were rewritten many times

until they satisfactorily conformed with all the department's requirements. This has been one unavoidable factor in delaying the start of the program. When all documents were in acceptable form, they were presented to the Executive Committee of the corporation for approval. Finally, in early September, the Commissioner of Insurance signed approval of all the documents and the program was launched. Since that time our whole endeavor has been to bring information to the physicians and solicit their enrollment as participating physicians. It is essential that a sufficient number of doctors be enrolled in any given area before sale of the contract to the public in that area will be justified.

I should like to show you now the organizational arrangement of Massachusetts Medical Service, so that you

portion. Next to the left, is the Interlocking Services Committee, composed of two members from Massachusetts Medical Service, two members from the Blue Cross and one member who sits on the boards of both corporations. Next, in the center, is the Executive Committee, which can be quickly called to handle such problems as demand immediate action and cannot await the regular meeting of the whole Board. Next to the left is the Financial Committee, which of course is of major importance in any corporate organization. Finally, at the extreme left, is the Central Professional Service Committee, also required by the bylaws, which will be the effective group for introducing, for consideration by the Board of Directors, expert, studied, accurate reports on vital medical matters which will be assured support by the parties

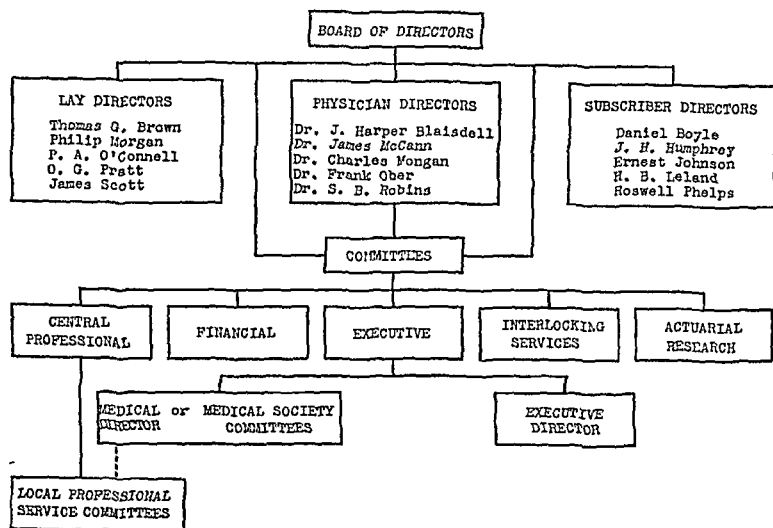

FIGURE 1 Committee Organization

may understand how the by laws that you adopted will be put into practical effect. Figure 1 shows the manner in which the Board of Directors has been organized into subcommittees, and the method of contact between the profession and the Board. The single block at the head represents the Board of Directors, the effective managers of the corporation. The next line of blocks indicates the membership of the three component groups in the Board — the lay, the medical and the subscriber representatives. The personnel of these groups has been publicized in the *Journal* and in the press so that you are quite familiar with these names. The next single block — committees — indicates the breakdown of this whole group into effective functional units, which can carry out the many and varied tasks of such a managerial group. In the next row of blocks are the five functional committees established within the Board. At the extreme right is the Actuarial Research Committee, the establishment of which was required in our by laws. The Insurance Commissioner believes that this should be an extremely active and important committee in guiding the future development of the cor-

poration. This will guard against hasty unstudied reaction in significant medical matters, which, if taken even inadvertently, might have a violently disruptive effect on the affairs of the corporation from withdrawals of participating physicians. In the early organizational work, this mode of approach has functioned effectively and efficiently. In the next line of blocks are the effective day by day administrative units of such an organization. At the extreme right is the executive director with, of course, his entire administrative office force, which works under his direction. At the left is the medical administration, either a medical director or voluntary medical society committees. The restrictive financial requirements of the State Department of Insurance compel us to initiate our venture through the medium of voluntary medical society committees. Furthermore, some of the already existing plans now state that in the early period of organization it is preferable to start with voluntary committees rather than with a medical director. The early financial problems are difficult and, with our local re-

quirements, are prohibitive of paying a medical director for some time to come. In the last block are the local professional service committees, one in each district medical society. Direct contact is maintained between the local groups and the Board through both the Central Professional Service Committee and the medical director or the medical-society committees.

Table 1 indicates the allotment of the personnel of the Board into the committee positions. Dr. Frank R. Ober, with an invaluable background of medical-society activi-

tors to meet periodically with the members of the corporation (the Executive Committee of the Council). Contact with the physicians locally in their districts is of equal importance, and this is achieved by the interrelation of the Central Professional Service Committee and the eighteen local professional service committees. Practically, it will probably be desirable for the president of the corporation to meet periodically with the chairmen of the local professional service committees. These arrangements and contacts minimize disruptive misunderstandings, and ef-

TABLE 1. *Committee Membership.*

CENTRAL PROFESSIONAL	FINANCE	EXECUTIVE	INTERLOCKING SERVICES	ACTUARIAL RESEARCH
Dr. Frank R. Ober, chairman Dr. J. Harper Blaisdell Dr. Charles E. Mongan Dr. Samuel A. Robins One layman (rotating)	Thomas G. Brown, chairman Dr. Charles E. Mongan James Y. Scott Daniel J. Boyle	Dr. James C. McCann, chairman Philip M. Morgan Dr. Frank R. Ober Harold B. Leland P. A. O'Connell	Dr. J. Harper Blaisdell, chairman Oliver G. Pratt J. H. Humphrey Two Blue Cross representatives George Putnam and Dr. Nathaniel W. Faxon	Roswell Phelps, chairman Dr. Samuel A. Robins Ernest A. Johnson

ties, is chairman of the Central Professional Service Committee. Mr. Thomas G. Brown, banker, is chairman of the Finance Committee. Mr. Roswell Phelps, director of statistics, State Department of Labor and Industry, is chairman of the Actuarial Research Committee. Dr. J. Harper Blaisdell, a member of the boards of both the Blue Shield and the Blue Cross, is chairman of the Interlocking Services Committee. We are fortunate to have as members of that committee Mr. Putnam, president of the Blue Cross, and Dr. Nathaniel W. Faxon, whose leadership has been outstanding in both medical and hospital affairs.

It is important, I believe, that you visualize now the functional arrangement of the entire organization which you have created. This is, of course, related to the appointment of committees from the medical group, which has been approved of by the Executive Committee of the Board of Directors. Figure 2 outlines the tentative functional plans. In the first line of blocks are represented two vital factors in the organization. There is the Council, the true representative body of the Society, which has fostered, approved and created Massachusetts Medical Service. It has established the personnel of the Executive Committee of the Council as the voting members of the corporation. The fact that these members of the corporation are at the same time members of the Council assures close and intimate contact with the medical profession. In the first line also is the broadly representative Board of Directors, elected to act as the managers of the corporation by the members of the corporation (the Executive Committee of the Council). Drawn down from these in the second row of blocks is the Central Professional Service Committee, which is empowered to initiate action within the Board of Directors on vital medical matters. These men, functioning as the representatives of the profession in the Board, must be keenly alert to the sentiment of the profession in these matters, to preserve the support and the participation of the physicians throughout the State. It is important that these representatives keep in intimate contact with the central representatives of the physicians and with the local medical groups. The first is accomplished by the requirement that action on vital medical matters be reported to the members of the corporation (Executive Committee of the Council) thirty days prior to action. The members, in close contact with the Council, may then send resolutions and recommendations back to these five physician directors. Practically, it will probably be desirable for these five physician direc-

fectually bind the whole profession together in support of this important endeavor.

Carrying out the day-by-day administrative work of the corporation entails activities in two distinct planes. One is the purely business administrative plane, and this will be carried out by the Blue Cross office force on a contractual basis; the Blue Cross will function as our salaried agent, and the medical corporation will pay its proportionate share of expenses. The second plane might be referred to as the medical-relations plane. All the remaining blocks refer to this segment of activity. Leading down from the Central Professional Service Committee, through which they will function, are medical advisory committees made up of voluntary committees from the medical society. The first two committees are the Medical Publicity Committee and the Medical Speakers Committee. In the interests of sound public relations with both the profession and the subscribers, it is important that the lay publicity agents be somewhat advised so that their methods will agree with professional practices. Anything that smacks of improper advertising or the bludgeoning of those physicians into participation who have honestly not yet made up their minds concerning the merits of the endeavor or that does not carry the distinct intentions of the profession to the public must be absolutely avoided. The second committee, the Medical Speakers Committee, has already been proved necessary by the innumerable requests for speakers. The third committee, the Medical Review Committee, is the profession's present substitute for a medical director. The four items listed below the committee block are problems that must occasionally be passed on by such a group. In the early stages of organization it is probably highly desirable that these matters should be passed on by a representative group of physicians, rather than by a single individual—a medical director. As experience stabilizes these problems they will disappear, and then they might be passed over to a medical director. In the early formative period it is possible that a medical director might be granted more power over these matters than the profession is as yet ready to delegate to one man. It seems advisable to pass these problems through the hands of a small medical review committee, let us say eight men. Probably they will be able to make a decision quickly on the vast majority of problems. For difficult technical problems they will have the Specialist Review Pool, made up of three members of each specialty. A particular technical problem in orthopedics they can pass

down quickly for decision to the three orthopedic surgeons, and such report as they receive back they can relay of physicians in the United States, and also all data obtained from the enrollment forms so far submitted to the

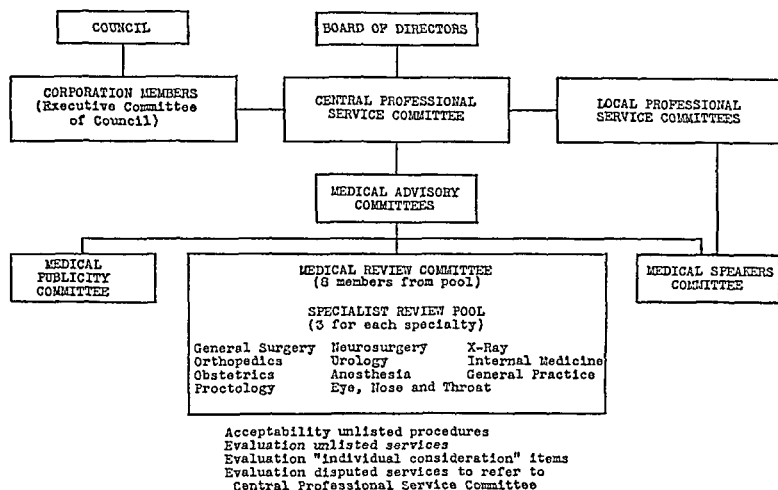

FIGURE 2 Functional Organization.

to the Central Professional Service Committee or to the administrative office for action. As the program broadens in coverage, additional specialist groups may be added to the pool.

For the present, this seems to be a rational method of procedure. With experience and time we shall undoubtedly find it advisable to modify this setup. However, in all matters—organization, contracts, schedules and so forth—I think we should feel that we have established a fair base from which to evolve gradually. Adjustments all along the line will prove inevitable. This, however, gives us a fair basis from which to proceed.

JAMES C. MCCANN, *Chairman*

APPENDIX NO. 7

REPORT OF THE MASSACHUSETTS STATE COMMITTEE, PROCUREMENT AND ASSIGNMENT SERVICE FOR PHYSICIANS

Since the last meeting of the Council, your committee has continued to work industriously. The medical military picture in Massachusetts has begun to clarify itself little by little and like any other picture has its good and bad sides.

Dr. J. J. Curley, of Leominster, one of the members of your committee, has resigned from it. He grew to feel that he could no longer be contented as a civilian and therefore applied for a commission. He is now a major in the Medical Corps of the Army. His services to your committee were invaluable and will be missed greatly but, on the other hand, he will make a splendid officer. His place has been taken by Dr. B. P. Sweeney, also of Leominster.

Within the past few weeks there have been sent to your committee figures dealing with the numerical distribution

Procurement and Assignment Service by Massachusetts doctors.

The age distribution of physicians in Massachusetts as of the year 1941 was as follows:

UNDER 35	35-44	45-54	55-64	65-69	70-74	75 AND OVER
2048 (27%)	1990 (26%)	1310 (17%)	1189 (15%)	550 (7%)	327 (4%)	298 (4%)

The enrollment forms submitted also yield the following information:

COUNTY OR DISTRICT	MEMBERSHIP OF MASSACHUSETTS MEDICAL SOCIETY (DISTRICT)	ENROLLMENT FORMS SUBMITTED (COUNTY)
Barretable	63	55
Berkshire	135	140
Bristol	295	293
Essex	526	504
Franklin	33	42
Hampden	351	348
Hampshire	80	90
Middlesex	1357	894
Norfolk	1073	416
Plymouth	164	171
Suffolk	691	691
Worcester	549	513
Miscellaneous		27
Total	5347	5440

These figures suggest that the majority of members of the Society have filled out their enrollment forms. That only 70 per cent of all the 7713 doctors in the State have done so, however, indicates that those who have been neglectful in supplying information concerning themselves still must be asked to fill out the forms at once. It would be helpful if all hospitals in the State reminded their regular and courtesy staff members to go to this trouble.

The discrepancy in figures from Middlesex, Norfolk and Suffolk is due to the fact that many members of Middlesex and Norfolk have offices in Boston and thus are listed

as belonging to Suffolk rather than to their proper district society.

Chief emphasis continues to be laid by both Army and Navy on the need for young medical officers. Since the commencement of its work your committee has been conscious of one serious handicap: we have declared "available" a great many young men after endeavoring to study each case individually and to be as fair and honest in our decision as to their classification as possible. Having declared a man "available," however, we soon learned that by no means all the individuals so designated had any intention of entering the armed forces.

It is a somewhat striking fact that random analysis of 100 enrollment forms sent in by doctors from all over the State shows that only one third put down Army or Navy as their first or second choice of how they hoped to serve the country during the national emergency and that a third were frank to admit they hoped to continue in private practice. These 100 forms included no names of men over thirty-five years of age. Most of these men are married and can claim dependents, thus under present Selective Service regulations they appear relatively safe from being drafted. About the only weapon with which to stimulate such men to make a patriotic gesture is that of public opinion. Fortunately, as time goes on, this becomes stronger; older physicians on hospital staffs and people in general are beginning to wonder audibly why certain young and healthy physicians are not in service. This sort of pressure is making itself felt. Thus each week we know of several newly appointed officers. The total number of members of the Massachusetts Medical Society who are commissioned has not been counted but it is fair to say that close to 1000 are now on active duty. We are informed that the enrollment from Massachusetts lags far behind that of most other states and that the need for officers from Massachusetts still is great.

We hear occasional grumbling that certain towns in the State have been depleted of young doctors. When such rumors are brought to our attention they are investigated at once through the district committees. There also has been sent us a list of men who put down as first or second choice on their enrollment forms a willingness to enter civil practice in other localities. Thus, so far there is little positive evidence of any real danger of medical depletion in any part of the State: in fact there still are a large number of young men in almost every district who should be encouraged to enter the armed forces rather than to remain behind. Machinery is now at hand to prevent or cure unnecessary depletion and we are endeavoring through Selective Service and the Medical Officers' Recruiting Board to perfect a workable method to stimulate young men to apply promptly for commissions who owe it to their country to do so.

The problem of industry in relation to Procurement and Assignment Service is beginning to assume larger significance than heretofore. We have received the names of all Massachusetts doctors who have expressed an interest in industrial medicine on their enrollment forms. This list is now being analyzed by the Committee on Industrial Health in co-operation with the Division of Occupational Hygiene of the State Department of Labor and Industry. Soon your committee will be in a position to assist the placing of men interested in industrial medicine and also to aid industries needing them to find properly qualified doctors.

The much debated question of the fate of the graduates of the substandard schools licensed to practice medicine

in Massachusetts has been solved. Your committee knows that an appreciable number of such doctors have received commissions in the Army irrespective of whether or not they were members of the Massachusetts Medical Society. The Surgeon General continues to decide in each instance how applications of this type shall be treated, and thus any direct action on our part is impossible.

On the whole, your committee believes that its work is progressing slowly but steadily along a well-ordered line. The committees in the several districts continue to work hard and conscientiously in their efforts to procure officers fairly, and also there is a fine spirit of co-operation on the part of hospitals, medical schools and various public-health officials.

APPENDIX NO. 8

REPORT OF THE COMMITTEE ON REHABILITATION

The last report of this committee to the Council of the Massachusetts Medical Society was dated May 18, 1942, and was approved by the Council at the last annual meeting. Since that time, no really important business has been transacted by this committee.

One member of the committee met with the Health Executive Committee of the Massachusetts Committee on Public Safety on June 25, 1942. Professor Curtis M. Hilliard, director of the Health Executive Committee, outlined in a general way the work which his committee had done. A considerable number of rehabilitation agents have been appointed and have reported some progress in their work. Ways and means of acquainting selectees rejected because of remediable defects or for other causes were discussed, and Professor Hilliard indicated that his committee would, so far as possible, take steps to inform those rejected what might be done to rehabilitate them.

Colonel Currier, of the Massachusetts Selective Service Headquarters, approved measures which had been attempted in this work of rehabilitation.

The federal government has done nothing further in this matter than was indicated in the report submitted at the annual meeting.

Your committee has, when called upon to do so, co-operated in every way with the Massachusetts Selective Service Headquarters in giving them such information as might reasonably and properly be given.

It seems now somewhat improbable that the federal government will, in the near future, undertake any extensive program of rehabilitation. If it is undertaken, the Massachusetts Medical Society will be ready to co-operate in an efficient manner with the federal or state government in this program.

CASE RECORDS OF THE
MASSACHUSETTS GENERAL HOSPITALANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 28461

PRESENTATION OF CASE

A forty-five year-old English machinist came to the hospital because of chills and back pain.

Sixteen days prior to admission the patient was awakened by a shaking chill, headache and a feeling of substernal oppression. He was vague about the duration of the chill, but it seemed to have lasted approximately two hours. He was not nauseated, did not vomit, had no pains and fell asleep promptly after the chill. The next day he felt well enough to get up but was weak and therefore did not go to work. On this day he noticed a small sore area on each knee about the region of the tibial tubercle, but could not account for their presence. He returned to work during the next two days. Four days after the initial symptoms he felt weak and after a bath again suffered with chills and fever. During this attack no feeling of substernal oppression developed. During the next four days he felt weak, anorexic and "not up to snuff." Eight days before entry he went to his physician, who told him that his liver and spleen were enlarged and advised him to have further studies made. He developed a dull aching nonradiating pain in the right scapular region, which continued to the time of admission but materially decreased in severity in the four days prior to admission.

It is of interest that the patient kept a dog, some rabbits and raised rats. He was bitten by one of the rats approximately two weeks prior to the onset of the present illness but the wound healed promptly. He had come to this country from Yorkshire, England, when nineteen years of age.

The family history was noncontributory.

Physical examination revealed a moderately well-developed and well-nourished man who appeared older than the stated age but did not appear acutely ill. The skin was sallow and seemed yellow. The sclerae had a suggestive yellow tint. On the left hand were the remains of two 1 cm. broken vesicles, which were said to have been mosquito bites. Several nontender lymph nodes, each approximately 1 cm. in size, were felt in the axillae and groin. Examination of the heart and lungs was negative. The midepigastrium seemed dis-

tended by a tumor mass, which was firm, did not pulsate and was not tender. It moved with respiratory excursions. The edge was felt six fingerbreadths below the right costal margin. In the left upper quadrant was a separate "grapefruit-sized," freely movable, nontender mass extending from the costal margin to the umbilicus. However, this mass did not move with respirations. One observer believed the mass was attached to the umbilicus.

The blood pressure was 130 systolic, 90 diastolic. The temperature was 98°F, the pulse 80, and the respirations 20.

The examination of the blood revealed a red-cell count of 5,540,000 with a hemoglobin of 80 per cent, and a white-cell count of 16,450 with 75 per cent polymorphonuclears, 22 per cent lymphocytes, 1 per cent basophils and 1 per cent eosinophils. The urine and stool examinations were negative, as was the blood Hinton test. The nonprotein nitrogen was 23 mg. per 100 cc., and the icteric index 5 per cent. The van den Bergh test was negative. A bromsulfalein liver function test showed 5 per cent retention. An echinococcus complement-fixation test was slightly positive, and an echinococcus skin test was positive. A study of the gastric acidity revealed a normal amount of free acid.

An intravenous pyelogram outlined only the left kidney, and this seemed to be normal. A retrograde pyelogram was done to visualize the right kidney; this revealed no abnormalities except that the right ureter was curved outward. A barium meal showed that the stomach was elongated and markedly displaced to the left, owing to a large epigastric mass. In the recumbent position a second pressure defect was produced on the greater curvature by an orange sized mass lying below and to the left of the stomach. There was no intrinsic disease of the stomach or duodenum. A barium enema showed that the colon filled well, with some hesitation at the splenic flexure. The transverse colon was pushed well down to the pelvis by a 10 by 10 cm. movable mass. In the lateral view the mass could be seen posterior to the colon and pushing it forward, but not connected with it. A chest film was negative.

On the eleventh day after admission an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. CHESTER M. JONES: I cannot recall having seen a protocol of a case that was so completely bewildering as this particular one. It says on the top of my copy, "For Differential Diagnosis." I am not sure I can present a differential diagnosis, but there are certain things here that are very interesting.

"He noticed a small sore area on each knee about the region of the tibial tubercle, but could not account for their presence." I think there are several red herrings and that is one of them. Whether I can keep clear of them remains to be seen.

This man had a sixteen-day story prior to admission, with an initial chill, fever and substernal oppression, weakness for four days, and then another chill and fever. We are not told what the height of the fever was. At the time of the last attack there was no substernal oppression. He must have felt sick and weak. Again, he had four days of weakness with indefinite intrathoracic symptoms and finally a decrease in severity of the subscapular ache or pain, not associated with cough or dyspnea and apparently not associated with any further manifestations of fever or chill, although we have to take that for granted from the history.

"He was bitten by one of the rats approximately two weeks prior to the present illness but the wound healed promptly." That is probably another red herring but it does raise questions.

Is Yorkshire a sheep country, Dr. Goulden?

DR. GOULDEN: Yes.

DR. JONES: "On the left hand were the remains of two 1-cm. broken vesicles, which were said to have been mosquito bites." A third red herring!

I suppose the left upper quadrant mass was thought by his physician to be spleen. The fact that it did not move on respiration is against its being spleen. The "attachment to the umbilicus" is a curious statement.

"The temperature was 98°F., the pulse 80, and the respirations 20." Those are very important facts, if they are facts, and if they continued the same throughout the course in the hospital. I assume he did not run a fever in the hospital. Is that right, Dr. Mallory?

DR. TRACY B. MALLORY: I find here that the temperature ranged between 100° and 102°F. rectally.

DR. JONES: There was a slight fever then, but without chills. It is of some importance, however, that there was no really abrupt temperature rise, no diurnal swing.

He had a definite leukocytosis and possibly a slight elevation of polymorphonuclear cells; the latter was not very striking, particularly with that degree of leukocytosis. The blood picture appears otherwise to have been normal.

There was no jaundice, and the suggestion on the part of the observer that the skin was sallow and the scleras icteric was not backed up by the presence of hyperbilirubinemia. The van den Bergh is an excellent check of the icteric index, and both were normal.

"An echinococcus skin test was positive." That is the fourth red herring. Whether that is the main fish or not, I do not know.

"An intravenous pyelogram outlined only the left kidney, and this seemed to be normal." The question is whether the right kidney was involved. I suppose they also wanted to see if there was displacement of the kidneys or ureters. At times this provides an excellent method of locating tumors in the abdomen.

At first glance the history seems to have no connection at all with the physical findings. Yet the physical findings were largely confirmed by careful x-ray studies, and showed a tumor outside the stomach and the urinary tract that displaced the stomach forward and to the left, and the colon forward and down. This seems to correspond with something that was felt in the left upper quadrant, which was called spleen by one man and a tumor attached to the umbilicus by another man, a tumor, moreover which did not move with respiration. There is no evidence of intrahepatic disease.

Finally, we have the perfectly flat statement, which I think cannot be doubted at all, that there was a positive echinococcus complement-fixation and skin test. Either this patient had a hydatid cyst or he did not. He might have had a hydatid cyst and a complication thereof or intercurrent disease with echinococcal disease that was purely coincidental, having nothing to do with the symptoms that brought the patient in. It can be pointed out, however, that echinococcal disease is symptomless for years, and also that 60 per cent of patients with echinococcal disease have cysts in the liver. This large mass on the right should have been liver until proved otherwise. I should say there is no reasonable doubt that the mass probably was the liver.

Symptoms arise from echinococcal disease only when there is a heavy liver or an accident, a rupture. It may involve other organs less frequently—the kidneys, the spleen and the peritoneal wall. It may involve the alimentary tract as well as the lungs. If there is an accident it draws the attention of the patient or his doctor to the disease. One accident of this type is the rupture of a cyst in the liver through the diaphragm into a bronchus, such as also occurs with liver abscess. That is ruled out here by the negative chest film. The hepatic cysts in echinococcal disease can rupture into the peritoneal cavity, into the retroperitoneal space and into the alimentary tract, and therefore it is entirely possible, if we disregard for the moment the onset of the initial symptoms, that this man has echinococcal disease, with a hydatid cyst of the liver, which probably ruptured into the peritoneal

cavity. The second mass, which was thought probably to be attached to the umbilicus, could be an inflammatory mass secondary to the spilling of the cyst contents. Another accident of echinococcal disease is suppuration of the cyst, but if such a patient has suppuration, he has the equivalent of a liver abscess, with more chills and fever and, by this time, other evidence of intrahepatic disease.

If the symptoms were not due to echinococcal disease, one has to consider a good many things ushered in by chills and fever and followed by a remission—in other words, a curious set of symptoms. He was bitten by a rat two weeks prior to the onset of symptoms. Could he have had rat-bite fever? Since the incubation period is fourteen days, the time is perfectly all right. Rat-bite fever runs a course of a few weeks. The fever may go down from a sharp peak for two or three days, with a second relapse higher than the first, and there may be a third, but the patient tends to get better all the time. I do not know how long the fever lasted in the first or second episode. There is frequently a skin rash in rat-bite fever. Also very frequently there is evidence of the rat bite. The liver and spleen are not particularly affected in rat-bite fever. This patient had a tremendous tumor, and if he had rat-bite fever, it is probable that he had another disease, which cannot be explained by that diagnosis. Furthermore, when the bite heals in rat-bite fever the healed wound subsequently breaks down and a scab is formed, which is rather sluggish in healing. There is no evidence of such a lesion. On the basis of his story the patient might have had spirochetel jaundice, but no jaundice was demonstrated at any time according to the laboratory data. Furthermore, in spirochetel jaundice there is not only fever but much more prostration, albuminuria of marked degree, and usually a slightly enlarged liver. This man had an enormous mass. He did not have spirochetel jaundice.

Could it be tularemia? He was taking care of rodents—rabbits and rats. Rabbits and rats carry tularemia. If he had had a bite from an infected rat he most certainly would have had a sluggish cutaneous ulcer, which would take weeks or months to heal. There was axillary adenopathy, but no streaking of the arm or local lesion. One could get an adenopathy without any evident wound, but this is uncommon. There was no involvement of the eyes, the ocular-glandular type of tularemia. There was nothing in the lungs. Furthermore the patient was not sick enough. The tularemia patient at the end of two weeks is very sick.

Could he have had typhus, which is associated with rats? The onset is not good for typhus. The clinical picture is associated with sudden onset, sudden headache and nausea out of proportion to anything else. At first, such patients are sicker than those with typhoid fever. The temperature is usually one of peaks and remissions. Furthermore, the big mass cannot be thus explained, and there was no skin rash.

I have no idea what this patient had unless it was echinococcal disease, with rupture of the cyst, probably into the peritoneal or retroperitoneal structures, forming a tumor mass, a cyst of the liver displacing the stomach, colon and right ureter, and a second tumor mass, which was not the spleen. It is obvious that he was explored because the mass was thought to be an echinococcal cyst.

My diagnosis is echinococcal disease.

Do you want to make a comment on the x-ray films, Dr. Holmes?

DR. GEORGE W. HOLMES: I am waiting for the signal.

DR. MALLORY: It might be amusing to put Dr. Holmes on the spot. As the record states, this patient was operated on and came back to the hospital ten years later with a feeling of discomfort in the left upper quadrant. After three days he felt a lump in the left upper quadrant and more x-ray films were taken.

DR. HOLMES: These films were taken ten years later?

DR. MALLORY: Yes.

DR. HOLMES: The stomach is displaced to the left, and the mass is on the right. The mass itself is dense and sharply defined and is perfectly consistent with a cyst. In these films the liver does not seem to be enlarged.

DR. MALLORY: Does the presence or absence of calcification in the wall of the chest mean anything?

DR. HOLMES: An echinococcal cyst should show some calcification of the wall. I suppose this fleck here is calcification, but there is not much and I cannot rule out some other kind of cyst. I think the story is consistent with echinococcal cyst.

DR. CASTLEMAN: Could it be a cyst of the pancreas?

DR. HOLMES: Yes. I am not attempting to say where it was or even whether it was in the abdominal cavity. It may have been in the pancreas. I do not believe it was in the spleen or kidney.

CLINICAL DIAGNOSIS

Echinococcal cyst.

DR. JONES'S DIAGNOSIS

Echinococcal cyst of liver, with possible rupture and secondary peritoneal involvement.

ANATOMICAL DIAGNOSIS

Echinococcal cysts of liver and gastrocolic omentum.

PATHOLOGICAL DISCUSSION

DR. MALLORY: At the first operation two echinococcal cysts were found. One enormous cyst had replaced practically two thirds of the liver substance. The second was smaller and was located in the gastrocolic omentum. The smaller cyst was removed. It was quite impossible to resect the larger cyst, so it was opened and some hundreds of daughter cysts were evacuated. The inside of the cavity was formalinized, and the surgeon backed out.

As you have heard, the patient was perfectly well for ten intervening years. Then he came in again with another large cyst—this time in the retroperitoneal tissues above the pancreas. Again the cyst was too large to resect, and once again it was treated by evacuation and formalinization of the lining of the cyst. On the last occasion the surgeon made no note of any significantly sized cyst of the liver. Apparently the treatment had shrunk the cyst down very effectively. On this second occasion the patient left the hospital symptom free and apparently well for the time being. Nothing was ever found to explain the history and fever on the first admission. Neither cyst had perforated, but as soon as he was operated on the fever disappeared.

CASE 28462

PRESENTATION OF CASE

An eighteen-year-old boy came to the hospital because of post-traumatic pain and swelling of the right knee.

Approximately two months prior to admission while playing baseball he was struck below the right kneecap by a thrown baseball bat. There was some immediate pain below the knee, which forced him to stop playing. However, he was able to walk home without great difficulty. The next day the knee was painful and stiff, and felt best when partially flexed. The pain was moderately severe and rather constant, and did not radiate. One week later, slight swelling developed. Two weeks after injury, while riding in an auto-

mobile, he was thrown sharply against the edge of the steering wheel striking the right knee just above the kneecap. This was a painful blow, and soon after the swelling at the knee became prominent and the knee became very tender. After the second injury he noticed increased difficulty in extending the leg and in walking, owing to the discomfort incurred by flexing the leg. He had lost 17 pounds during this two months' illness.

The family and past histories were noncontributory.

Physical examination disclosed a slender, pale boy who appeared chronically ill. As he stood he could not bear all his weight on the right leg, and walking was very difficult owing to "weakness and pain in the right knee." Examination of the heart, lungs and abdomen was negative. There was a moderately soft, fluctuant swelling with a fluid wave about the right knee, extending from the level of the anterior tibial tubercle onto the lower third of the thigh. There was only slight fullness of the popliteal space. The patella was ballotable and was displaced laterally. There was increased local temperature over the knee, and tenderness to palpation along the medial aspect of the patella. The sharply demarcated edge of the quadriceps muscle was felt above the patella in the midline and anteriorly and medially over the femoral condyle. However, the patella moved slightly when the quadriceps femoris muscle was contracted. Knee flexion to a 95° angle was permitted.

The blood pressure was 110 systolic, 68 diastolic. The temperature was 101°F., the pulse 100, and the respirations 22.

Examination of the blood revealed a red-cell count of 4,700,000 with a hemoglobin of 80 per cent, and a white-cell count of 13,000 with 79 per cent polymorphonuclears, 9 per cent lymphocytes, 10 per cent mononuclears and 2 per cent eosinophils. Examination of the urine was normal except for occasional white cells and epithelial cells in the sediment. The blood Hinton test was negative. A tuberculin test with a 1:10,000 dilution was positive. The sedimentation rate was 2, 18, 22 and 38 mm. at fifteen-minute intervals.

An x-ray film of the right knee demonstrated a diffuse swelling in front of, below and above the patella, extending about one third the distance up the thigh and downward to the region of the tibial tubercle. The film of the chest was negative.

Soon after admission, the knee joint was aspirated, and 100 cc. of blood-tinged, rather viscous fluid was recovered. This was negative for aerobic and anaerobic bacteria. On the fourth day after

admission, a course of orally administered sulfadiazine was begun. A total of 78 gm. was administered during the succeeding seventeen days, without remarkable effect. The temperature continued to rise each evening to approximately 101°F ., and the pulse rate remained fast, varying usually between 90 and 115. During the course of sulfadiazine, the urine at times showed a + test for albumin and occasional granular and hyaline casts, and on one occasion red blood cells were noted. No sulfadiazine crystals were found in the urine. The sulfadiazine level in the blood was not known to have exceeded 9.0 mg. per 100 cc. The fluid intake and output was satisfactory.

On the fifth day after admission the knee joint was again aspirated, and 50 cc. of thick, tenacious, bloody material was recovered. This was found to have a red-cell count of 36,000 and a white-cell count of 7600. In the differential count there were 48 per cent polymorphonuclears, 48 per cent monocytes and 4 per cent lymphocytes. Cultures for aerobic and anaerobic organisms were negative. Four days later the joint aspiration was repeated, and a similar material recovered. The red-cell count was 105,000, and the white-cell count 41,000 with 90 per cent polymorphonuclears, 3 per cent lymphocytes and 7 per cent monocytes. There was a fairly large amount of atypical mucin in the material. In the examination for mucin a large amount of precipitate formed but in small pieces, which did not cling to a stirring rod. The sugar of the joint fluid was 6 mg. per 100 cc., and at this time the fasting blood sugar was 82 mg. Three days later the joint fluid was bloody, thick and slimy, with a red-cell count of 33,000 and a white-cell count of 96,000, with 85 per cent polymorphonuclears, 14 per cent monocytes and 1 per cent lymphocytes. The fluid had a sugar content of 6 mg. per 100 cc., and at this time the fasting blood sugar was 98 mg.

An operation was performed twenty-nine days after admission.

DIFFERENTIAL DIAGNOSIS

DR. FRIEDRICH W. KLEMPERER: Mucin if precipitated with acetic acid normally forms a precipitate that is stringy and ropy. Mucin may be present in normal quantity, but may not show the typical precipitate with acetic acid. In this case one sees flocculation or sometimes just turbidity. This atypical behavior is due to depolymerization of mucin, which usually is a sign of infection, but may also be found in other kinds of arthritis.

Here we have an eighteen-year-old patient who sustained a definite injury to his knee. This was immediately followed by pain, but there were grad-

ually increasing swelling and disability following injury. He had a second injury two weeks later, which aggravated these symptoms but did not otherwise change the picture. During the two-month period following the onset of symptoms we know that the patient lost 17 pounds. Nothing is said in the history about constitutional symptoms or fever, but the remark in the examination on admission that the patient appeared chronically ill indicates that he must have had moderately severe constitutional symptoms, and probably fever. The description of the physical findings in the knee seems slightly confusing. There was undoubtedly a large effusion in the knee, and some periarticular swelling. I cannot make out where the edge of the quadriceps muscle was, but it was apparently held in transverse position. Whether this means more than soft-tissue swelling or whether there was some atrophy around the joint that made the muscle edge stand out more, I do not know. There was displacement of the patella, but it does not say to what degree. I assume that a large amount of fluid can displace the patella slightly. In the x-ray report nothing is mentioned about bone involvement, and the picture as described indicates an effusion and soft-tissue swelling.

DR. TRACY B. MALLORY: Here is a diagram that may help you.

DR. KLEMPERER: According to this diagram it does not seem as if the patella were displaced markedly.

May we see the x-rays?

DR. GEORGE W. HOLMES: I presume this film was taken of the chest to make certain that the patient did not have metastasis from some sort of tumor, and I should interpret the chest as essentially negative.

This film was taken to bring out the soft-tissue shadows about the knee. It is somewhat underexposed, whereas the other films were taken in the usual manner. I think we can be quite certain there is no disease of bone demonstrable by x-ray. They are very satisfactory films and are entirely negative.

DR. KLEMPERER: How much atrophy of the bone is there?

DR. HOLMES: Practically none. There is a tremendous amount of thickening of the soft tissue in front of the bone, and it is rather unusual in that it extends below the patella. An accumulation of fluid may extend up into the thigh but it is unusual; I do not know that I have ever seen it extend so far below the patella. The joint space might come down that far, but I cannot be sure that such is the case.

DR. KLEMPERER: He had a large effusion?

DR. HOLMES: He did. Another queer thing is the lack of demarcation between the tissues in that area. The swelling may have been due to edema, but ordinarily when there is fluid in the joint space, one can see details in the tissue.

DR. KLEMPERER: Traumatic arthritis is practically ruled out by the clinical story of weight loss, temperature and leukocytosis. Another very strong point against traumatic arthritis are the findings in the joint fluid. Traumatic effusions never contain a large number of white cells. The highest count we have had was 5800, the average being around 1000; furthermore, the polymorphonuclears never exceed 35 per cent. One never sees low sugar values in the fluids of traumatic arthritis. The mucin should have a good quality and precipitate in a typical manner. Of course there are other kinds of arthritis that can be precipitated by trauma, or the trauma might represent the localizing factor in infectious arthritis.

A tumor should be ruled out too. The history of fever, the constitutional symptoms and leukocytosis are not in favor of tumor. The same holds for the fluid findings. The fluid in a case of tumor resembles that of traumatic joint fluid unless the tumor is infected later. One never sees cell counts up to 100,000, with a predominance of leukocytes. Furthermore, in most cases the mucin precipitates well and the sugar is high. On the basis of the fluid, I am inclined to rule out tumor unless secondary infection supervened. The x-ray film might possibly be interpreted as showing a soft-tissue tumor, but I should think that it represents marked synovial swelling, with periarticular edema that obscures the details of a large effusion.

Rheumatoid arthritis usually presents an entirely different picture. The onset is preceded by prodromal symptoms, weight loss and general fatigability, of which we have no indication, and the joint involvement is usually polyarticular and symmetrical. However, 18 per cent of the cases in our series were atypical. The joint involvement may be monarticular at onset. The disease occasionally follows injury and may be accompanied by severe constitutional symptoms, fever and leukocytosis. Clinically, the picture could be this. The absence of bone involvement, the periarticular swelling and the effusion are consistent with rheumatoid arthritis. However, again on the basis of the fluid findings, I shall rule out rheumatoid arthritis. The white-cell count in rheumatoid arthritis ranges from 600 to 66,000, with an average of about 5000 to 10,000. The highest white-cell count in this case was 96,000, and only a small number of the leukocytes can be accounted for by blood that may have entered the joint during the tap. The polymorphonuclears in rheumatoid

arthritis vary from 5 to 95 per cent. One even more important finding is that, although the joint involvement was of short duration, eight or nine weeks, at the time of the joint tap, the aspirated fluid contained practically no glucose. We have never seen an early rheumatoid effusion with a low sugar. During the first few weeks the sugar in the fluid has about the same level as that in the blood. After six months we have seen it go down to something like 30 mg. per 100 cc., and only after a year is there an occasionally negative sugar, as in this case. This fluid finding indicates that rheumatoid arthritis is extremely unlikely.

This brings us down to the septic arthritides. The first is gonococcal arthritis. There is no history of genitourinary infection. Nothing is said about a primary focus, such as urethritis or prostatitis. There were no chills. The temperature was not high. The joint symptoms were not very acute. The joint was not red or extremely tender. The duration of the effusion in gonococcal infection usually does not last close to three months, as in this case. However, a low-grade infection might possibly produce a picture like this. Sterile joint fluid is often found in milder cases, when the organism has invaded the synovial membrane but not the joint cavity. However, these are rather avirulent cases and never show a cell count up to 100,000, and absence of sugar in the joint fluid. I should say if this were gonococcal arthritis it should show either a positive culture or the white-cell count would be less and the sugar higher. Septic arthritis due to pyogenic organisms, — staphylococcus, streptococcus or the pyocyanus bacillus — is unlikely. There was no primary focus of infection, and no portal of entry to the joint is mentioned. The patient did not have chills, and the findings were not typical. The duration is too long for a septic joint. The patient either gets well or worse within two or three months.

The other organisms that might account for a monarticular arthritis should be mentioned. In a generalized meningococcal infection, arthritis might be the first symptom, but the nature of the fluid is against it.

I shall mention in passing the other diseases in which arthritis is a secondary feature of the general disease, such as pneumococcal infection, dysentery or typhoid fever, although I do not want to consider them seriously. Lymphogranuloma inguinale as the cause of arthritis almost always produces polyarticular involvement, and purulent fluid is never found, so far as I know. Syphilis is ruled out clinically as well as serologically.

This brings us to tuberculosis of the knee. The clinical history is consistent with tuberculosis.

Trauma is known to precipitate or determine the localization in tuberculous arthritis in about 50 per cent of the cases in some series. The slow progression of symptoms, the weight loss and the moderate temperature without chills are all consistent with tuberculosis. The physical findings about the knee are also typical. The large amount of synovial and periarticular swelling with atrophy of the muscles early in the game is characteristic. Large effusions are not frequently found but are possible. The absence of a pulmonary lesion is not very important. Only about half the patients show lung lesions, and from the tuberculin test we know that the patient must have had some previous tuberculous infection. The most significant finding is the character of the fluid. The atypical appearing mucin, the high cell count and the low sugar are very typical of tuberculous arthritis. In other kinds of arthritis the level of the sugar is usually in inverse proportion to the severity of the involvement and to the white-cell count in the joint fluid. However, in tuberculosis, relatively low counts with absent sugar are quite characteristically found. Of course, there is a somewhat puzzling variation in the fluid findings. In the first, the cell count was 7000, and then it continually went up so that the second was 30,000 and the last 96,000. This is unusual for tuberculosis, but it is also unusual for any other kind of arthritis. I am thinking of one possibility. This fluid was described as slimy, thick and tenacious, and in such turbid fluid the white cells occasionally clump and one cannot obtain a representative sample of fluid or an accurate cell count. Whether this was so, I do not know, but it is certainly a possibility. On account of the findings I am inclined to think that tuberculosis is the most likely cause of this patient's difficulties.

Of course in any kind of unusual joint disease undulant fever should be considered. This would be an atypical case, but the typical clinical picture is often lacking and frequently one does not find the leukopenia that is characteristic. The joint involvement is usually polyarticular and without objective signs. Severe signs like this are very unusual, and only a few cases have been described where just one joint was involved and pus was recovered from that joint. These cases are open to the question whether they really represent brucella infection, because the organism was found in none of them. Brucellosis is a possibility, although I think it is very unlikely.

I believe the operation performed on the twentieth day was a biopsy, and I also think that tuberculosis was found in the synovial membrane.

DR. MALLORY: Have you anything to add to the question of tuberculosis, Dr. Holmes?

DR. HOLMES: The absence of any evidence of disease in the bone or joint cartilage is against tuberculosis, although the bone may be negative in cases of tuberculosis of the synovia. I do not see how we could rule that out.

CLINICAL DIAGNOSIS

Pyogenic infection of knee.

DR. KLEMPERER'S DIAGNOSIS

Tuberculosis of synovia of knee joint.

ANATOMICAL DIAGNOSIS

Tuberculous bursitis.

PATHOLOGICAL DISCUSSION

DR. MALLORY: I see no member of the Orthopedic Service here to describe the operation. As Dr. Klemperer suggested, the operation was done for biopsy. I judge from the operative note that the surgeon, to his considerable surprise, found a cavity almost immediately after going through the skin. This cavity contained hemorrhagic material and was lined with a semicaseous surface. Biopsy from this wall showed tuberculosis. Further exploration showed that the cavity extended well up into the thigh beneath the quadriceps muscle, and that a fistulous tract extended downward lateral to the patella, which accounted for the swelling below the patella noted by Dr. Holmes. The surgeon did not open the knee joint but tapped it and obtained clear fluid. We have no certain evidence whether or not the knee joint was directly involved. In one of the various taps presumed to have been of the joint it was remarked that fluid was obtained after barely puncturing the skin. So it is possible that several of the fluids examined did not represent joint fluid but came from the inflamed bursa. However, the chemical findings led to the correct etiologic diagnosis whether the site of involvement was the joint or not.

DR. HOLMES: The homogeneous density of the joint in front should have made us suspicious.

DR. MALLORY: Certainly most of the infection was outside. I cannot say whether there was any in the joint or not.

MATERIAL for early publication should be received not later than noon on Friday.

THE JOURNAL does not hold itself responsible for statements made by any contributor.

COMMUNICATIONS should be addressed to the *New England Journal of Medicine*, 8 Fenway, Boston, Massachusetts.

REHABILITATION AND PREHABILITATION

NINETY per cent of the youths from sixteen to twenty-four years of age in low-income families are in need of medical or dental care. Two thirds of the whole group, which is believed to be representative of some 12,000,000 American youths, are physically fit for any kind of work; one third of them are limited by health defects in what they can do. These figures, contained in a recent joint release of the United States Public Health Service and the National Youth Administration, are based on physical examinations of 150,000 out-of-school youths on work programs of the NYA. Despite the well-known fact that statistics are often misleading, such figures, as well as the data provided

by the Selective Service examinations, furnish food for thought.

In the first place, American youth, physically impoverished as it may be, is not so unhealthy as the large scale examinations of 1917 and of 1940-1942 have led many critics to believe. The standards used must be considered, and although impaired eyesight, certain degrees of dental caries and pronated feet must be classified as defects, they do not necessarily impair the health or interfere with physical vigor.

In the second place the discovery of true disease or of major defects and their subsequent treatment are of vast importance to the individual as well as to industry, to the war effort and to the tax-paying public, as are the discovery and correction of the remediable minor defects.

In the third place the physical examination itself is held up for review, to determine its effectiveness and its time-honored inadequacies and the changes in it that are necessary from time to time to make it fulfill the functions for which it is intended and with which it is credited.

Out of the Army examinations and rejections has come a new interest in an old word—rehabilitation. Those whom the military machine cannot immediately use must not be left discarded by the wayside. They must be listed, repaired and reclassified—made ready for future military service or for whatever service they can best be fitted into. The next step in the program is an anticipatory one: the finding, before they come of useful military or civil age, of those who require correction of defects, in order that they may not be later rejected. This is prehabilitation, and it is gradually but surely becoming a potent factor in the readying of the manpower of the Nation.

THE NEWS

THE first number of a new bulletin from the Massachusetts General Hospital, entitled *The News* and dated October, 1942, has been received. This pamphlet is really a continuation of the *Massachusetts General Hospital Bulletin*, established in 1913,

which was subsequently interrupted by the activities of World War I. Publication was resumed in 1919, only to be suspended in 1926. Again, in 1928, a new bulletin was started, but this was given up during the financial depression of 1932. Thus a spark has been kept alive, although intermittently the flame has almost died out.

There apparently is a need for some medium to spread the news about a great hospital, much of which cannot find its way into the annual report or, if it does so, is too late to have anything but historical value. News quickly becomes uninteresting if allowed to lie too long on the shelf. The new publication is therefore welcome, particularly at this time, for it brings to one's attention the splendid effort made by the voluntarily supported hospitals toward the war. In the present number are not only a photograph and data concerning the present Massachusetts General Hospital unit, the Sixth General Hospital, but also a long list of men who are serving in various branches of the armed forces.

MEDICAL EPONYM

SCHULLER-CHRISTIAN'S DISEASE

Professor Artur Schuller (b 1874), of Vienna, wrote a paper, "Ueber eigenartige Schadeldefekte im Jugendalter [Peculiar Skull Defects in Childhood]" which was published in *Fortschritte auf dem Gebiete der Rontgenstrahlen* (23:12-18, 1915). He described three cases, and a translation of his conclusion is as follows:

Each of these briefly outlined cases represents a noteworthy and extraordinarily uncommon condition. Common to all three is the fact that there were extensive defects in the skull that developed without pain and without any cerebral symptoms of any sort—practically without symptoms of any kind. Neither could there be discovered in these cases any of the recognized causes for such defects in the skull. Of interest, too, is the presence of a hypophyseal symptom complex in two of our cases, namely dystrophia adiposogenitalis in the first, and diabetes insipidus in the second. Finally, the relatively rapid disappearance of the defects, which was clearly perceptible by x-ray, constituted a noteworthy feature of the second and third cases. We suggest the name 'geographical skull' [*Landkarten schadel*] as a suitable term for the peculiar appearance of the x-ray defects that we have described.

Dr. Henry A. Christian (b 1876), Hersey Professor of the Theory and Practice of Physics, Harvard Medical School, described "Defects

in Membranous Bones, Exophthalmos and Diabetes Insipidus. An unusual syndrome of dystrophia adiposogenitalis" in the *Medical Clinics of North America* (3:849-871, 1920). After presenting a case and referring to those described by Schuller, he concludes:

A case is presented where, in a girl of five, there occurred the symptom-complex of very extensive defects in the skull bones, exophthalmos and diabetes insipidus. Only 2 other cases of this condition could be found in the literature. Diabetes insipidus suggests that the symptom complex is due to a disturbance of pituitary function. Both of the other 2 reported cases showed evidence of disturbed pituitary function.

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE ON MATERNAL WELFARE

ANALYSIS OF CAUSES OF MATERNAL DEATH IN MASSACHUSETTS DURING THE YEAR 1941

MEDICAL CAUSES (continued)

The previous two issues of the *Journal* have discussed the maternal deaths associated with heart disease and pneumonia. The following is a résumé of the remaining 8 deaths in the group allocated to medical causes.

Two of these were definitely associated with hypertension. The first case was that of a patient admitted between three and four months pregnant who was admitted to the hospital unconscious. She was known to have had a high blood pressure for three years; in 1940 when she had a miscarriage at five and a half months, her blood pressure was 240 systolic, and 120 diastolic. Prior to entry she had suffered a cerebral hemorrhage with right hemiplegia and had a blood pressure of 250 systolic, 150 diastolic. An autopsy was performed. From the medical standpoint there is every argument against the occurrence of pregnancy in this case, for it definitely irritated the hypertension and caused the catastrophe.

The second case was that of a twenty-five-year-old woman, approximately five months along in her first pregnancy, who gave a history of repeated attacks of sore throats with cardiac involvement. She was hospitalized because of a blood pressure of 190 systolic, 120 diastolic, and signs of cardiac embarrassment. Digitalization improved the cardiac condition but in spite of this the kidneys shut down entirely; the nonprotein nitrogen varied from 34 to 55 mg. per 100 cc, and the urine showed a ++++ test for albumin and casts. She died undelivered of uremia. The comment made on the foregoing case applies

here. Neither of these patients should have been allowed to become pregnant, if one looks at it from a purely medical point of view, and in the event of pregnancy, abortion should have been advised.

There were two cases of meningitis. One of these was tuberculous in origin and occurred in a patient approximately five months pregnant. She was seen at home twice by her local physician and sent to the hospital practically moribund, with a stiff neck, a temperature of 104°F. and a pulse of 150. Death occurred forty-eight hours later. Although cultures and smears for the organism were negative, the diagnosis was based on the spinal-fluid findings. This patient died undelivered.

The second case of meningitis occurred in a patient who had had a normal delivery and was discharged on the tenth post-partum day. She returned one month later with the story that two days before entry she had been seized with a severe headache, which was followed by a stiff neck. Lumbar puncture revealed cloudy fluid, and 20 cc. of antimeningococcus serum was administered. Blood culture was positive for streptococcus, and death occurred two days after admission. This death had nothing whatsoever to do with the obstetric condition; it just happened to be co-existent.

The next 2 cases in this series were allocated to gastric ulcer. The first of these was a woman who was delivered normally at home of her fifth child. Four days after delivery she vomited blood and had tarry stools, and arrived at the hospital two days later in very poor condition. She was transfused, but death resulted from massive hemorrhage from the stomach. This was a most unfortunate catastrophe that had nothing to do specifically with the pregnancy.

The second patient was delivered by low forceps, when approximately eight months pregnant, of a stillborn infant. Vomiting had occurred a week before delivery, and death resulted from hemorrhage two days post partum. It is possible that the hemorrhage was due to an esophageal varix, but no autopsy was performed to confirm this. This case again has no particular association with pregnancy.

One death was due to ulcerative colitis. A patient who had had diarrhea for four or five weeks entered the hospital when about four months pregnant, a spontaneous miscarriage occurring four days after entry. She ran a septic temperature and died sixteen days after delivery, in spite of sulfonamide therapy. Autopsy revealed ulcerative colitis and generalized peritonitis; there was no apparent perforation of the bowel, but pneumoperitoneum

was discovered. Although there was no visible rupture of the uterus, there is some question whether instrumental interference with the pregnancy had been attempted.

The last of the deaths allocated to medical causes was due to pulmonary tuberculosis and occurred in a woman who was apparently seen for several months by her physician before tuberculosis was diagnosed. She reached the sanitarium practically moribund, and death occurred the day following the normal delivery of a stillborn infant. It is a sad commentary on medicine in Massachusetts that this case of tuberculosis could have run so serious a course before consultation was held or the diagnosis made.

WAR ACTIVITIES

CIVILIAN DEFENSE

EMERGENCY BASE HOSPITALS

The Medical Division of the United States Office of Civilian Defense, through its regional medical officers and the state chiefs of Emergency Medical Service, has now made emergency provision for the establishment of a chain of emergency base hospitals in the interior of all the coastal states. They will be activated only in the event of an enemy attack that necessitates the evacuation of coastal hospitals. Each base hospital will be related to the casualty receiving hospital that has been evacuated, and it is expected that the staff will be recruited largely from the parent institution.

To meet a sudden and unexpected crisis without delay, arrangements have been completed with state authorities for the prompt taking over of appropriate institutions in the interior of the state for this purpose and with local military establishments for the transportation of casualties and other hospitalized persons along appropriate lines of evacuation.

More than 150 hospitals in the coastal cities are in the process of organizing small affiliated units of physicians and surgeons, who will be prepared to staff the emergency base hospitals if they should be needed. These units are composed of the older members of the staff and those with physical disabilities that render them ineligible for military service, and of women physicians. The doctors comprising units are being commissioned in the inactive reserve of the United States Public Health Service so that, if called to duty, they may receive the rank, pay and allowances equivalent to those of an officer in the armed forces.

Dr. George Baehr, chief medical officer of the United States Office of Civilian Defense, states that the members of these affiliated hospital units will continue to remain on an inactive status for the duration of the war, unless an enemy attack in their region necessitates the transfer of casualties to protected sites in the interior. Their commissions may be terminated on their request six months after the end of the war, or sooner if approved by the Surgeon General. Such approval will be given in the event such officer desires active duty in the Army or Navy.

MISCELLANY

TUFTS COLLEGE MEDICAL SCHOOL

President Leonard Carmichael, of Tufts College has recently announced the gift of a tract of land in downtown Boston from Mr A Shapiro, of Brookline. The property, consisting of five buildings on Tyler Street was formerly owned by Denison House and adjoins property on Harrison Avenue recently purchased by the school. It is adjacent to the hospitals and dispensaries of the New England Medical Center, of which Tufts is the teaching base.

The land was purchased, according to Mr Shapiro so that there will be plenty of elbow room around the proposed three-quarter million-dollar medical building. President Carmichael said that the gift was prompted by the donor's appreciation of the rural medical extension program being developed by the Tufts faculty at the New England Medical Center, a project whereby many local communities in Maine were benefiting from the school's extension of laboratory and diagnostic services, training of local hospital technicians and assistance in organizing emergency medical protection such as a state wide network of civilian blood banks. The donor expressed hope that the gift would induce similar contributions from other laymen.

The President announced that well over half a million dollars has now been subscribed for the new building and efforts are being made to complete the fund so that the medical school, which is the principal training center for New England doctors, may build as soon as conditions permit.

NOTE

Professor Edwin J Cohn, head of the Department of Physical Chemistry at Harvard Medical School, recently delivered the third Alvarenga Prize Lecture before the College of Physicians of Philadelphia and the Philadelphia County Medical Society. The title was 'Plasma Proteins: Their properties and functions'.

CORRESPONDENCE

RACE, COLOR AND RELIGION*

To the Editor In the recent exchange of correspondence over the industrial health questionnaires in the October 8 issue of the *Journal*, it is unfortunate that Dr O'Hara regarded the entire matter as 'ill-natured' and that Dr Muller allowed himself to be drawn into personal attack on Dr O'Hara. As a result, the real issue, which is an important one, was obscured.

The point is simply this: the question about race, color and religion is an old stand-by of those who subvert the principles of democracy by discrimination in employment or elsewhere. It is, no doubt, true—as Dr O'Hara maintains—that certain employers desire these data. But since they have absolutely no bearing upon medical ability, their only use would be as a discriminatory weapon. The selective service registration, which Dr O'Hara cites by way of analogy, requests information about color, height, weight, hair color and so forth purely for identification purposes and there is clearly no discriminatory intent. On the other hand it has been the policy of the United States Employment Service for some time to refuse this type of information to employers, and the latter if they hold war contracts, are expressly for-

bidden to discriminate against able workers for reasons of race, color or religion.

For these reasons the Committee on Industrial Health ought not to have made itself the agent for perpetuating unfair and un-American employment practices. Today, physicians of all racial and religious groups are entering the armed services, creating a serious problem of properly redistributing the remaining doctors to civilian needs. At such a time our country needs the right men in the right places, and we can ill afford the luxury of weeding out capable physicians on the basis of blood composition, skin pigmentation or church affiliation. Fortunately, doctors are so scarce now, and industry so badly in need, that organized medicine could, if it wished, play an important role in breaking down these undemocratic practices of discrimination. May we suggest that the Massachusetts Medical Society handle this question as our government does and refuse prospective employers any information that could be used in a discriminatory fashion?

AVRAM GOLDSTEIN, H M S 44, *Chairman*
New England Region, Association of Internes and Medical Students

368 Longwood Avenue
Boston

* * *

Mr Goldstein's letter was referred to Dr O'Hara, chairman of the Committee on Industrial Health, Massachusetts Medical Society, whose reply was as follows:

To the Editor By the use of such words and phrases as 'questionnaire,' 'real issue,' subvert the principles of democracy, discrimination and unfair and un-American practices and by direct implication that the Massachusetts Medical Society somehow has prying motives that are beneath the dignity of our government, Mr Goldstein forces me to write again, much as I regret to ask for more of your space.

It is hard for me to believe that anyone who has seen our little registration form, or who knows the members of our committee, or is in any way familiar with the temper of the Council to whom the committee reports and is responsible can fail to be impressed with the nature of this correspondence, be it good or ill. I can assure Mr Goldstein and all those who habitually fear persecution and evil that our committee has no inquisitorial designs or desires. We do not care whether such persons register with us, but if they do, we shall earnestly endeavor to treat them in the way by which industrial health can best be served. Only secondarily are we interested in helping them as individuals. We believe our country's peril makes this our only proper attitude, and we are taking it seriously.

In closing, it is my belief that the interns and medical students of New England, in whose name the writer designed to dip his pen, are worthy of a higher expression of their interests and activities.

DWIGHT O'HARA, M.D.

FELTY'S SYNDROME

To the Editor The paper, 'Rheumatoid Arthritis associated with Splenomegaly and Leukopenia,' which appeared in the September 10 issue of the *Journal*, interested me particularly because the authors omitted a discussion of certain facts that may be of significance in explaining the etiology of this syndrome, originally described by Felty.

They failed to mention, for instance, that, in the cases reported by Hanrahan in 1932 and by Craven in 1934, the

patients experienced significant relief of symptoms and a rise in leukocytes to a normal level following splenectomy. In a third case, recently reported by Steinberg, the patient showed similar improvement.

Most disappointing was the fact that there was no attempt to correlate these cases with the newly recognized syndrome, primary splenic neutropenia, originally described by Wiseman in 1939. A detailed discussion of this disease has recently been given by Wiseman (Wiseman, B. K., and Doan, C. A. Primary splenic neutropenia; a newly recognized syndrome, closely related to congenital hemolytic icterus and essential thrombocytopenic purpura. *Ann. Int. Med.* 16:1097-1117, 1942). Seven such cases, exhibiting leukopenia, fever, hyperplasia of the bone marrow and splenomegaly, have been reported. In most of these, there was some arthritis.

The failure to establish infection as the primary cause of rheumatoid arthritis suggests the possibility of an error in metabolism as being an underlying factor. It is interesting to speculate the nature of this error. The occurrence of arthritis in people with primary splenic neutropenia and the improvement of the joint symptoms following splenectomy may offer a new concept of the pathogenesis of Felty's syndrome, as well as rheumatoid arthritis as a whole. If this type of arthritis occurs as a result of a chronic decrease in the number of circulating leukocytes, it is not unreasonable to suspect it may occur as a result of some pathologic alteration of the fundamental character of the leukocytes in the absence of leukopenia.

There is not enough evidence at present to assume that rheumatoid arthritis associated with splenomegaly and leukopenia and primary splenic neutropenia are the same or related syndromes. There is enough evidence, however, to warrant further study with this possibility in mind.

WILLARD H. WILLIS, M.D.

Slocum-Dickson Clinic
258 Genesee Street
Utica, New York

BOOK REVIEWS

A Primer on the Prevention of Deformity in Childhood. By Richard B. Raney, M.D., in collaboration with Alfred R. Shands, Jr., M.D. 8°, cloth, 188 pp., with 88 illustrations. Elyria, Ohio: National Society for Crippled Children, Incorporated, 1941. \$1.00 postpaid.

There has long been a need for a volume of this type. It describes in a clear, simple manner the usual deformities of the locomotor system, how they occur, and how they can be prevented. There are numerous drawings of deformities and of apparatus. It is shown that most skeletal deformities can be prevented, often by the use of simple measures. The book should be especially helpful to orthopedic nurses, physiotherapy technicians and social workers, as well as physicians, on whom rests the responsibility for the prevention of deformities.

Arthritis in Modern Practice: The diagnosis and management of rheumatic and allied conditions. By Otto Steinbrocker, M.D. With chapters on painful feet, posture and exercises, splints and supports, manipulative treatment, and operations and surgical procedures by John G. Kuhns, M.D. 8°, cloth, 606 pp., with 321 illustrations. Philadelphia: W. B. Saunders Company, 1941. \$8.00.

The authors have succeeded admirably in reducing to a reasonable compass the essentials of recent progress in

arthritis. The classification adopted is that commonly used in America, based on the belief that the proliferative type is the result of toxic influences, whereas the degenerative has no direct association with infections.

In the opinion of the reviewer, the chapters on fibrositis and on local and regional analgesic injection comprise the greatest contribution to knowledge of painful musculoskeletal disturbances. These, alone, make the book worth having. The inclusion of chapters on the technics employed in the management of arthritic sequelae adds to the usefulness of the book.

Our Sex Life: A guide and counsellor for everyone. By Fritz Kahn, M.D. Second revised edition. 8°, cloth, 460 pp., with 41 illustrations. New York: Alfred A. Knopf, 1942. \$5.75.

This general treatise of twenty-three short chapters divided into seven hundred and thirty-five numbered sections is a translation of a German work. The book possesses some of the merits and demerits of recent German treatises for the sexual instruction of laymen: the colored illustrations are above average, and the range of topics is wide enough to take up most questions that trouble the average person; on the other hand, the book is not always accurate. There is a tendency to lean toward the bizarre in some of the case histories. Although better books are available for general instruction, this is a worthwhile addition to popular literature. Certainly, it is a great improvement over what was available a decade or two ago.

After giving a description of male and female structures and functions, the author discusses the hygiene of sex life, birth control, abortion, contraception, sterility, disturbances in sex life, such as impotence, frigidity and premature ejaculation, and the commoner diseases of sex life. Part VII is devoted to prostitution, and Part VIII to juvenile sex life; Part IX deals with the sex life of unmarried people.

Nutritional Deficiencies: Diagnosis and treatment. By John B. Youmans, M.S., M.D. Assisted by E. White Patton, M.D. 8°, cloth, 397 pp., with 16 illustrations. Philadelphia: J. B. Lippincott Company, 1941. \$5.00.

It is a paradox of modern civilization that, with the progress of society, concomitant problems have developed, one of the major ones involving the poor nutrition of the masses. The extreme poverty afflicting large numbers of men, women and children created medical as well as social difficulties. Vast clinical material, tantamount to mass experimentation, afforded opportunities for study that rapidly supplemented animal experimentation. Of the nutritional difficulties, vitamins play a major role.

The author has admirably sifted the data in a book characterized by an orderly and lucid presentation of the important aspects of deficiency diseases, with the greater emphasis on vitamins. Also included, however, are protein and mineral deficiencies.

Summaries, tables and laboratory procedures are other valuable features of the book. For one not in a position to undertake the laborious task of reviewing the massive literature, this volume will provide an adequate substitute.

The reviewer cannot refrain from echoing the sentiment that, after all, a normal diet in a normal person is an adequate diet. It is deplorable to contemplate the colossal sums of money expended in "over-the-counter" sales of vitamins to persons who are not the most in need.

NUMBER 21

THE SEQUELAE OF WAR HEAD INJURIES*

D Denny Brown, M.B., D.Phil., F.R.C.P.†

BOSTON

EARLY in 1939, Air Commodore C. P. Symonds, consultant in neurology to the Royal Air Force and an authority on the subject of disability from head injuries, was planning the establishment of a central air-force hospital in England for neurologic problems from head injuries in flying personnel. He recognized the variety of special problems inherent in the assessment and adequate treatment of head injury in modern warfare, particularly the peculiar interrelation of surgical, neurologic, ophthalmologic and psychiatric problems involved. Colonel Hugh Cairns was, he found, already interested in neuro-surgical organization for the British Army, and it was proposed that the two plans be coalesced in a combined services hospital for head injuries. Arrangements were completed with the enthusiastic co-operation of the Directors General of the Army and Air Force medical services, but not until some months after the outbreak of war did the hospital begin to take shape. It was eventually opened in February, 1940, as an army hospital with some specially seconded Royal Air Force personnel. It received both Army and Royal Air Force casualties. I had the honor of being placed in charge of the Medical Division, which was entrusted with the original plan of Air Commodore Symonds, closely interrelated with the Surgical Division to which Colonel, now Brigadier General, Cairns was consultant. Air Commodore Symonds was not only the consultant to the Medical Division but also organized and supervised the Registry of Head Injuries, which is making a most valuable research correlation of all the data made available by this unique unit.

The following account is concerned with the assessment and treatment of prolonged sequelae of head injuries, although other types of neurologic

disturbance also claimed attention. The surgical aspects of acute injuries have been commented on elsewhere.^{1,2} From the beginning, it was evident that, as had been foreseen, the proper treatment of the late effects of head injury under service conditions required a more than usually thorough preliminary examination. The large numbers of possible factors causing failure to return to duty following a reasonable convalescence from head injury (six weeks was the arbitrary time adopted) may be resolved into two chief categories—organic and psychoneurotic. It is essential to assess these factors accurately, for their treatment and disposal differ greatly.

The Registry has already collected complete data, including follow-up, on well over 1200 cases of head injury handled by the hospital. Complete analysis will ultimately be published by the British Medical Research Council, which finances this aspect of the work. The kind of problem involved can be estimated from my personal notes of the last 400 cases of persistent disability admitted by me for assessment. It must be emphasized that, although the hospital received acute head injuries from a large area and a majority of cases of persistent disability from all areas, these figures are highly selective, and complete data regarding all head injuries or all casualties cannot be published at present. I purposely omit the patients with recent injuries who made rapid recoveries. Out of the 400 cases of unduly delayed convalescence, 38 patients had suffered gunshot wounds of the head, 13 injuries to the head in aircraft crashes, 303 head injuries from other trauma (motor-cycle or other accidents with vehicles, tanks and so forth), and 46 from recurrence of symptoms from old head injury dating from before the war. Of these 400 men, 22 (5.5 per cent) were suffering from *traumatic epilepsy*, 116 (29.0 per cent) from other *organic defects*, and 262 (65.5 per cent) solely or chiefly from *psychoneurosis*. In the group of 38 gunshot wounds, 3 pa-

*Presented in abbreviated form at the annual meeting of the Massachusetts Medical Society, Boston, May 27, 1942.

†Professor of neurology, Harvard Medical School, director of the Neurological Unit, Boston City Hospital, and Captain, Royal Army Medical Corps Reserve.

tients suffered from epilepsy, 19 were still disabled by organic (structural) disorders, and 16 by psychoneurosis. Of these, 21 were subsequently fit to return to duty, and 17 were discharged unfit. The proportion of the 400 returned to duty was almost exactly the same.*

It is clear that disorders such as hemiplegia and aphasia following a laceration of the brain are the result of damage to structure; on the other hand, a prolonged disability, such as insomnia, tremors, depression and fear of crowds, following a trivial head injury in a person who was previously prone to such symptoms is palpably psychoneurotic. The actual decision is, however, seldom so clear cut, and with increasing experience of all classes of injury from a variety of circumstances, more and more involved mixtures of organic and functional sequelae were defined by modern methods. Thus, to quote extremes, the aircraft pilot who has made a perfect recovery from a surgical head wound, has shown himself fit for every form of strenuous physical exertion, and pesters everyone to be allowed back to duty may develop a serious flying error on return to his squadron owing to a previously undisclosed nervous anxiety caused by the terrifying circumstances of his accident. Apart from the danger of further accident, the subsequent treatment for this neurosis involves a waste of time that is saved if the liability is diagnosed earlier. The patient who has suffered an apparently trivial head injury and later wanders, with loss of memory, is sometimes shown by the electroencephalogram or subsequent attacks to be suffering from epilepsy, although his original wandering fugue was hysterical and his memory is recoverable under Amytal. The patient behaving in a clearly neurotic manner may be found to have a xanthochromic spinal fluid, and the real reason for the failure to return to efficient duty of a patient with optic atrophy in one eye may be related not to his vision but to his anxieties about his relatives at home. An unsuspected abscess may be discovered by a chance air encephalogram, and an unsuspected but fundamentally important emotional factor may slip out in a casual remark.

Moreover, in the modern soldier, the tremendous tension of modern warfare — the noise, the rush of movement, the variations in climate and, above all, the heightening of individual responsibility — renders accurate assessment of great value in the decision regarding the return to duty and the kind of duty; such a decision is even more important in the airman, and may present the utmost difficulty in officers and commanders. When downgrading of responsibility appears desirable

*Symonds has published in the July, 1942, issue of the *Proceedings of the Royal Society of Medicine* the results of a follow-up of 871 cases, including the 400 mentioned here, that show 68 per cent successful return to service duties.

on medical grounds, or when the question of invaliding out of the service arises, further psychologic considerations complicate the picture and must be carefully weighed regarding individual personality if successful adjustments are to be achieved.

The medical services of the United States are no doubt fully alive to and prepared for the inevitable problems that will arise in these respects, but discussion of them, in the light of over eighteen months' experience of this kind of work before I was transferred to my present assignment, may be of interest.

GENERAL CONSIDERATIONS

Traumatic Epilepsy

The incidence of traumatic epilepsy following head injury will no doubt be a surprise to some, especially in view of the low figures of Sargent³ after World War I (4.5 per cent in 18,000 cases) and of Stevenson⁴ (1.5 per cent in 17,300 cases). But in the present whole series, the incidence was even higher than in the 400 cases mentioned above, for the Registry had filed 53 cases (16 focal and 37 generalized) out of a larger group of 630 fully documented consecutive patients. Of these, 22 had had attacks within one month, 16 in one to six months, 8 in six to twelve months, and 5 in two to five years. Of the 22 having convulsions within one month, only 6 had suffered gunshot wounds.

Traumatic epilepsy is a complication of localized destruction and scarring of cerebral tissue, particularly from so-called "open injuries," when the dura has been penetrated. The attacks had rarely remained sufficiently localized to give good results from excision of the scar (1 case in 400 head injuries, and this was a closed head injury). Closed head injury undoubtedly can give rise to traumatic epilepsy, as Symonds⁵ has remarked; but the liability to epilepsy is not proportional to the severity of injury, even with prolonged unconsciousness and resulting intellectual defect. Of 87 patients with post-traumatic amnesia longer than seven days, only 3 suffered from epilepsy (2 generalized, 1 focal). One of these had shown evidence of focal brain injury, and it is likely that this was present in the other 2. Traumatic epilepsy is therefore not the result of a generalized damage to the brain. These figures are in accordance with those of Ascroft,⁶ who analyzed material from World War I after an interval of seven to twenty years; in his series, the incidence of epilepsy was 34 per cent and, in cases in which the dura had been penetrated, 45 per cent. In other series, Wagstaffe⁷ found a general incidence of epilepsy in 10 per cent of 377 cases, Rawling⁸ in 25 per cent of 425 cases, and Credner⁹ in 38.2 per cent in 1990 cases after five years. Cred-

ner noted that 81.1 per cent of cases with dural penetration develop epilepsy. The variability of these figures depends on the manner of selection of the head-injury series, and the length of time under observation. The Registry will afford more accurate statistics as time passes. It must be borne in mind that the material discussed here includes few mild head injuries (concussion with full recovery within six weeks) and not many of the severer injuries, and consists of selected problem cases of intermediate type.

This situation is serious, and few surgeons appreciate the disabling possibilities of the simplest dural wounds. The problem is even more complicated in the common type of modern bomb or splinter injury, in which small fragments of metal and bone scatter widely through the brain, and lodge in the most inaccessible places. Such foreign bodies appear to cause no trouble, for they are seldom infected, and after débridement of the most superficial, the others may remain until more is known about their epileptogenic properties. So far as present hypothesis goes (Penfield¹⁰), it is the cerebrodural scar that is epileptogenic, not necessarily the foreign-body reaction, and experience with these very small splinters of bomb casings certainly bears this out.

The finding of Wagstaffe,⁷ Symonds⁵ and Ascroft⁶—that epilepsy occurring within the first four weeks after injury has an excellent prognosis—was fully borne out in our cases. The electroencephalogram shows widespread activity of epileptic type in many cases of laceration of the brain without clinical evidence of convulsions (Williams¹¹), and this also rapidly subsides without aftereffect. There is, however, an exceptional and rare type of case in which a relatively trivial injury has been followed by persistent severe fits of a generalized kind, with an electrical record in the intervals between the attacks resembling that of deteriorated idiopathic epileptics. A previous constitutional liability to epilepsy is then to be suspected, and the prognosis is poor.

Other Organic Disabilities

Of the other consequences of structural damage to the brain, hemiplegia, paraplegia from wounds to the vertex, hemianopia or scotomatous field defects and dysphasic-dyspraxic disorders are obviously serious disabilities. Much can be done to rehabilitate such men for some form of civilian employment, with training in special skills. The same training facilitates the speed of recovery of lesser disorders of motor function, sensation, speech and vision. Persons who are really effective in designing exercises in muscle re-education, or to obtain sensory co-ordination, and who can direct

speech therapy and visual exercises are few. Moreover, such treatments are time consuming. The experienced physician therefore early selects cases with a good prognosis for return to duty and retains them in the service hospital, advising early discharge of the remainder to civilian rehabilitation centers. The general nature of the problem is well described by Goldstein¹² in a monograph in which he summarizes his experience in World War I. He gives an excellent description of methods again found useful both in accurate assessment and in rehabilitation. It is not practicable to rehabilitate all men in a service hospital that has a large waiting list.

In cases requiring bony repair, with fractures into a frontal sinus,¹³ with retained foreign bodies, and with jaw, facial, ophthalmic and other injuries, surgical consultations and conferences regarding the main disability are indicated; if necessary, the patient is transferred to a surgical division, to return later for the neurologist's supervision during final convalescence. In some cases of recent injury (and usually in hitherto unsuspected scalp wounds), a subdural hematoma, an abscess or necrosis of the bone requires direct surgical relief.

POST-TRAUMATIC GENERAL CEREBRAL SYNDROME

Prominent in the sequelae of head injury are headache, usually associated with vertigo, difficulty in concentration and insomnia, with or without depression. This whole group, variously described as the "postconcussion syndrome," "post-traumatic general cerebral syndrome" (Foerster¹⁴) and "minor contusion syndrome" (Symonds¹⁵) is by far the commonest symptom complex that develops out of craniocerebral injuries. It follows all kinds and degrees of head injury, although many writers have commented on its absence in many cases of severe laceration of the brain (Russell,¹⁶ Schaller,¹⁷ Strauss and Savitsky¹⁸ and others). A general discussion of the symptoms is given by Symonds.¹⁵ Schaller¹⁷ subdivides cerebral post-traumatic disorders into the "post-traumatic psychoneurotic state," with symptoms of headache, dizziness and hysteria, and the "post-traumatic concussion state (encephalopathy)," with loss of concentration, defective memory and vertigo. This presupposes that headache, dizziness and so forth are psychoneurotic symptoms, and some frankly ascribe the combination to a compensation motive. Others^{16, 19} have pointed to its occurrence in cases without compensation factor of any kind. The subject has been very adequately reviewed by Strauss and Savitsky.¹⁸ Penfield and Norcross²⁰ claim that post-traumatic headache is due to meningeal adhesions demonstrable by their special

technic for showing subdural air, and that "the patient's description of his symptoms makes the diagnosis certain and allows the understanding physician to recognize the true sufferer." They do not specify the elements in the description on which this sanguine statement is based. It is probable that headaches of organic and psychoneurotic types should have different clinical characteristics. With my associates, I attempted, unsuccessfully, to define such differences as may exist. We found that clearly demonstrable meningeal scarring was occasionally the site of localized ache, but usually not. Subdural air has been seen in encephalograms without previous injury (Lemere and Barnacle²¹) and is not regarded as of value in diagnosis. On the other hand, the depressed psychoneurotic patient frequently complains of a steady, dull discomfort over the whole head, unaffected by posture or external events, except excitement. This type of headache is well recognized as of psychoneurotic origin. But this was not the answer. The common paroxysmal generalized or one-sided headache—diffuse but usually frontotemporal, affected by posture as well as exercise or excitement, rising to intensities of sharp pain followed by numbness, and associated with swimminess on or after stooping, with loss of concentration and, usually, periodic insomnia—was as commonly associated with frank psychoneurosis as with severe brain injury. One difference, however, that probably accounts for the denial of many that such a post-traumatic syndrome is associated with severe head injury, is its delayed onset in these cases, so that at the time of discharge from the hospital or the completion of usual convalescence, the syndrome has not yet appeared.

Among other names, the group of symptoms is commonly called the "post-concussion syndrome." If by concussion is understood immediate loss of consciousness due to injury of the head, associated with loss of memory for this time, and retrospective loss of memory of the injury and the events immediately preceding it, it is certain that the post-traumatic general cerebral syndrome can occur without concussion.

Something must be said of the pathology of concussion. Experimental evidence has shown that concussion is not associated with any cerebral lesion recognizable by the naked eye, or by the microscope with any staining process at present available.²² It is not due to any effect on cerebral blood vessels, although changes in circulation accompany its later stages. It has a characteristic effect on the cerebral electrical record,²³ and is a phenomenon common to any nervous center subjected to sufficiently sudden physical stress. It

is a transient paralysis of nervous function. In head injury, it is generalized, and is produced by sufficiently sudden acceleration or deceleration of the head. It is thus often absent in crushing injuries, even though they cause multiple fractures and other damage,²² for the head may not be subjected to change in velocity.

It is common knowledge that extradural hemorrhage, subdural hemorrhage or cerebral contusion can be produced by an injury that does not concuss the patient. These effects are due to local tears or distortions. Clinical evidence shows that medullary contusion, with or without subarachnoid hemorrhage, can be produced without concussion.²⁴ In war surgery, the absence of concussion in penetrating injuries of the brain has been commonly noted (Léri,²⁵ Denny-Brown,²⁴ Denny-Brown and Russell²² and Eden and Turner²⁶). Concussion is the outcome of *general commotion* of the brain, which is slighter or absent when penetration occurs, especially with small fragments.

Recently, fat embolism has been held responsible for concussion (de Gutiérrez-Mahoney²⁷). This, however, did not occur in my experimental work on concussion.^{22, 23} Furthermore, the recognized clinical disorder due to fat embolism is delayed in onset and characterized by unmistakable features in pathology (Osnato and Giliberti²⁸ and Robb-Smith et al.²⁹). In all the cases of acute head injury in this series, there was only 1 patient who clearly suffered from fat embolism—that is, fever, petechiae and fat in the urine. The patchy damage it causes in the cerebral cortex is identical with the patchy cell changes in the cerebral cortex found months or years after injury that are described by Winkelman and Eckel³⁰ and that are considered by them to be the basis of the post-traumatic general cerebral syndrome.

The common types of severe head injury show various combinations of a series of separate clinical entities, including medullary contusion, subarachnoid hemorrhage, general cerebral concussion, cerebral contusion, laceration, intracerebral and extracerebral hemorrhage, subdural collections of blood or fluid, skull fracture and, sometimes, fat embolism. Each or all may be followed by the syndrome in question. Despite the influence of posture, one should regard the syndrome at this stage as a *particular mode of reaction to head injury*, without specific identification with either an organic or a functional basis. In this sense, it is directly comparable to the "effort syndrome," recognized by Wood³¹ and others as related to either cardiac disease or cardiac neurosis and, in both, a type of reaction to cardiac symptoms. Only in this way does it appear possible

to reconcile the appearance of the post traumatic syndrome in association with a great variety of types of injury. Some illustrative examples indicate the general nature of the problem.

CASE 1 Driver R. L. B., aged 21 was thrown from an army car on January 10, 1940. There was a retrograde amnesia for a few seconds and a blank in memory for 10 minutes after the injury. The patient then vomited and was taken to a hospital. There was a bruise in the right temporal region, but no other injury. Right sided headache continued for 3 days and then ceased. The patient

had nightmares of falling and of being wounded. He was sure that he had fractured his skull and damaged his brain.

He responded immediately to psychotherapy but relapsed, with further headache and complaint of dizziness at the prospect of return to duty, and was eventually discharged as permanently unfit.

This patient presented the post traumatic syndrome in characteristic form, with typical postural reaction to the headache and even syncopal attacks, yet the vasomotor instability had antedated

FIGURE 1 Case 2

In the lateral view of the skull just below the arrow is a small picture of entry of the bomb fragment with underlying gray flakes of bone and small metal particles. The main metal fragment had crossed the cavity of the skull to lie on the tentorium where it is seen through the mastoid cells (to the right of the line x). The anteroposterior view with the ventricles filled with air shows enlargement of the ventricle on the side of entry in the metal fragments (m and x).

felt well and was discharged to duty after 3 weeks. In May, after 10 days of continuous fighting, he became very exhausted and once fainted for a few minutes. He came through Dunkirk without incident but a month later began to suffer from generalized headache every 3 or 4 days lasting all day, more pronounced with exertion or excitement and associated with dizziness on movement. In the next month, he fainted four times, usually after some physical exertion. His mother and a cousin had suffered from psychoneurosis, and his mother had fainted on several occasions. He had been an average scholar, had no ways being a worrying sensitive fellow, and had once fainted at a camp at the age of 12 years.

He was of pale complexion and poor physique, but had no sign of injury to the head and no abnormal physical signs. X-ray films of the skull showed no bony injury. An electroencephalogram was normal. The red-cell count was 4,175,000 with a hemoglobin of 85 per cent. After prolonged interviews the patient recollected being terrified of traffic after his accident and had vivid recollections of it for some weeks. He explained how he then became less nervous, but after Dunkirk had vivid recollections of the fighting and became terrified of the possibility of pain or the sight of blood. He said: "I could not go through that again." He developed fears of traffic or air raids, and

the relatively slight injury, and the whole syndrome was considered to be a result of constitutional psychoneurosis.

CASE 2 Corporal Y., aged 22 years, sustained small cuts in the scalp from fragments of a bomb in May, 1940, and was concussed for 5 minutes. The scalp wounds healed rapidly, and he did not complain of any further disorder. In August, during another bombing, which did not harm him, he developed headaches on exertion, dizziness on bending, emotional lability and insomnia. These symptoms increased in intensity, and after 4 months of disability from them, examination revealed an excessively nervous man without sign of damage to the skull or nervous system. He admitted tremor during the second bombing and that he had at that time deserted his post to take cover, even though he had not been discovered. He confessed inability to face further service and further disclosed a matrimonial tangle of considerable proportions. X-ray films disclosed unexpectedly, several bomb fragments in the brain (Fig. 1) and a small parietal portal of entry only a few millimeters in diameter. The patient failed to make adequate response to psychotherapy, and since there was a family history of severe nervous breakdown, he was discharged.

In this case, in spite of the presence of foreign bodies, the post-traumatic syndrome was considered to be purely psychoneurotic.

The following case is an example of local cerebral contusion without concussion.

CASE 3. Guardsman A. C., aged 23, was injured on May 15, 1940, defending a canal bank at Louvain. He was struck tangentially by a bullet, which tore a 7.5-cm. hole in his steel helmet and made a cut 3.5 cm. long in the midoccipital scalp, 5 cm. above the occiput. He did not lose consciousness, and fired three more shots, but could not see plainly — "like through a mist." He crawled back to a trench and walked a mile to his medical officer. In this time, his vision was becoming dimmer, and when he arrived at his dressing station he could not distinguish light from dark. The wound bled severely and after morphine the patient remembered no more until 2 hours later, when he awakened in a casualty clearing station with severe headache but could see a little better. For

times, a cough caused a sharp stab but no lasting pain. Bending made the pain worse; later, the patient was more comfortable when lying down. In the 4th week, he could read small print, but the effort precipitated headache. In the 6th week, reading no longer caused headache, and his distant vision was clear for the first time. Headache on exertion became very infrequent, although of the same type and lasting for some hours. By the 9th week, the

FIGURE 2. Case 4.

The lateral view of the skull shows metal and bone fragments. The portal of entry is very small and partly obscured by the lowest metal fragment. The ventricles were partially filled with air, and the patient was lying occiput down, so that there is a fluid level. The anteroposterior view shows distortion of the ventricle toward the fragments. All disability was nevertheless relieved.

the next few days, intermittent, severe frontal headache, radiating to the nose, lasted for hours and continued for the next 3 weeks, at first daily, with three bouts in the last week. Vision slowly improved, at first for near objects, with a shimmering mist blurring anything farther away than his own hand. No hallucinations occurred. The headaches usually appeared in the afternoons, and were immediately made worse by any movement. At other

FIGURE 3. Private W.

These are lateral and posteroanterior views of the skull of a patient who was not concussed by the penetrating bomb fragment, which crossed the frontal lobes to lodge above the opposite orbit. Flakes of bone lie directly beneath the point of penetration. After débridement, including removal of the bone flakes but not the metal fragment, he made an excellent recovery, without epilepsy or other disability.

patient had ceased to have headache except after very severe exertion or excitement, and felt well in all other respects. There had been no faints, and he had slept well all through. His vision was 20/30 in each eye, there was no field defect, the wound had satisfactorily healed, and x-ray films showed no bony damage. After a graduated convalescence, he returned to duty and remained well for at least a year.

This patient evidently suffered a contusion of the occipital lobes, but was not concussed. The local

brain injury conditioned a post traumatic headache, but at no time was there any symptom that could be construed as being emotional or psychoneurotic. The subsidence of the headache paralleled

local brain injury. They were cited to show that contusion, concussion, foreign bodies and even scarring of the brain substance are not necessarily factors in inducing continued headache. Further-

FIGURE 4 Case 3

These electroencephalograms were made from bipolar parietal leads on the left side A, seven days after the injury, B, three weeks after the injury, and C, ten weeks after the injury. The time tracings show 1 second notches. The disturbance was identical in all other leads on both sides at each stage.

led the disappearance of the contusion as judged by the disappearance of the visual symptoms.

A similar history, with concussion and brain injury and spontaneous recovery follows.

CASE 4 Private R. W. D., aged 21, was injured in Flanders on May 22, 1940. He remembered the whistling of a bomb and that he threw himself on the ground. He remembered vaguely an explosion and lifting sensation and then nothing until he was being bandaged with a field dressing less than 5 minutes later. His steel helmet had been blown off by the bomb explosion, and he had a scalp wound, he had difficulty in expressing himself although he was well aware of his surroundings. He had headaches but no giddiness for the next 2 weeks. After 2 weeks, he could speak a few words, and gradually his speech returned completely in the next 2 months. He had at no time any difficulty in understanding written or spoken speech or in writing what he wished to say. After 3 months, he complained only of headache after severe exertion. Examination at this time revealed a slight right facial weakness, and a stellate scar in the left frontoparietal region, but no other abnormality. Speech was occasionally hesitant. A ray film showed a small opening in the left parietal bone, with small fragments of bone and bomb splinters in the brain and with some enlargement of the ventricle by the resultant scar, as shown by air encephalograms (Fig. 2). Electroencephalograms showed a persistent low voltage wave focus just posterior to the wound of entry. No further surgical treatment was advised, and with graduated exercise the patient was entirely free from headache by October, returning to duty in November. He had remained well when last heard from, approximately 6 months later.

The patients in Cases 3 and 4 had excellent personal and family histories, and thus no doubt contributed to their complete recoveries, despite severe

more, 'organic' headache is not necessarily associated with postural giddiness. There were a number of other similar cases of gunshot penetration with complete recovery. In one such patient, a fragment traversed both frontal lobes (Fig. 3).

Three cases of transverse through and-through bullet wounds of the frontal lobes showed severe intellectual impairment but no evidence of post-traumatic syndrome. Other cases, with severe paralysis, also failed to develop the syndrome, but possibly because the disability prevented exertion, which is one of the provocative factors.

Another type of case, however, is more frequently associated with persistent post-traumatic syndrome, and in its severest form is usually called 'traumatic delirium' or 'traumatic stupor',³² according to whether or not restlessness is prominent.

CASE 5 Sergeant R., aged 24, sustained a bilateral wrist fracture and a scalp bruise on the right temple in a motor cycle injury on November 14, 1940. He was admitted in coma,* with bleeding from the right ear. The pupils were small and equal, the tendon jerks brisk, and the plantar responses flexor. The pulse was 128 to 132, and the blood pressure 135/90. After 24 hours, the patient responded to questions by inarticulate noises, and resented interference, there was photophobia, and the plantar responses became extensor. After 4 days, he began to make intelligible remarks, such as 'What's that?' 'Don't do that' and 'Is Mother there?' He was deeply confused,

*The Commission on Brain Injuries of the British Medical Research Council has compiled a standard definition of terms commonly used in head injury.³² Of a 'traumatic coma' is preferred to 'unconscious' and defined in terms of reaction to stimuli.

and the next day, in response to the question about how he felt, said: "Not too bad, doctor. I go to the hospital every morning." His restlessness increased, especially at night, and he shouted if interfered with. He was doubly incontinent. After 14 days, he could mumble his name and address in response to questioning, and occasionally showed his teeth or followed a finger with his eyes, if requested. The plantar responses returned to normal, and the incontinence lessened and disappeared. The patient remained grossly disoriented in time and place, and had

FIGURE 5. Case 5.

These lateral and anteroposterior views (occiput down) of the skull, after air encephalography, show general dilatation of the ventricular system.

no memory of the day before, or even what meals he had had that day. X-ray examination of the skull was entirely negative. The cerebrospinal-fluid pressure was 170 mm., and the protein was 35 mg. per 100 cc.; no cells were present.

Gradually, co operation and orientation returned, passing through a stage of confabulation, with some perseveration in speech and ideas but no dysphasia. The memory was severely affected, and the patient often relived events of years or months before. Christmas Day, in the 6th week of his illness, was the first current event to remain in his memory and also subsequently marked the end of post-traumatic amnesia. The retrograde amnesia, at first of 3 months with "islands," gradually narrowed down to an irreducible minimum of a week.

The patient steadily improved, but with persistent slowness and difficulty in concentration. His memory remained

grossly defective (except for retaining serial digits, but he had been an accountant). He was emotionally labile and disturbed by his difficulty in concentration.

Not until he began to get up each day did he complain of headache, generalized, increased by movement, concentration, noise or cough and lasting for some hours on his return to bed. He felt giddy if he turned quickly, and occasionally faint. When, after some weeks, he was given graduated exercise, he reacted by a "catastrophic reaction," failing suddenly on every test at an easy stage, and became depressed and introspective. Only with return to lesser grades and with great patience was he induced to further graduated activity. When well enough to care for himself, he was discharged for further rehabilitation in a civil hospital.

Throughout his illness, this man showed gross electroencephalographic abnormality. Large slow waves at the rate of 1 per second were present throughout the two hemispheres for the first fortnight (Fig. 4), and then gradually lessened with the appearance of faster rhythms. After 3 months, the base line still showed traces of the slow waves. There was not at any time a focus of abnormality.

This patient never showed any evidence of damage to a localized part of the brain. There was no evidence of fat embolism, although the urine was not examined for fat. The cerebral disorder was generalized and severe, and was followed by persistent intellectual deficit. It is an open question whether the emotional disorder and the post-traumatic syndrome were directly induced by the injury or were a psychoneurotic reaction to the patient's awareness of his mental limitation. The family and past histories were irreproachable; he had been a successful businessman before enlistment. An air encephalogram after 3 months showed generalized dilatation of both lateral ventricles, indicating generalized cerebral atrophy of mild degree (Fig. 5). In view of the persistent electroencephalographic abnormalities, which after 3 months took the form of small runs of slow waves at times (possibly indicating some tendency to epileptiform manifestation), the whole disturbance was regarded as directly consequent on the traumatic damage to the brain, and visualized as an extreme example of concussion.

Slighter varieties of this type of disorder, which might be called traumatic coma followed by confusion, are not uncommon. All degrees are met, down to such brief events as are more usually termed concussion, with correspondingly lesser degrees of, or absence of, residual intellectual impairment. An intermediate degree is illustrated by the following case.

CASE 6. Gunner J. B., after a motorcycle accident, was deeply comatose for 24 hours, and confused and restless for 21 days, with normal cerebrospinal-fluid pressure and contents. The electroencephalogram showed large slow generalized waves all this time. After a slow convalescence, — 3 months, — the patient was able to saw logs without symptoms. The electroencephalogram was not quite normal, and all memory and other intelligence tests gave a poor response (for example, the patient retained only six digits). On return to duty after 4 months, never having had a headache, he immediately broke down, became very emotional, complained of severe headache on any exertion and of giddiness on bending or turning suddenly or on looking up or down, insisted that he was

anxious to return to duty, and rapidly responded to psychotherapy. At the urgent request of his commanding officer, he was allowed to return to duty after further convalescence, subsequently relapsed and was eventually

to one or both of two factors, unduly prolonged coma and confusion following the injury, indicating concomitant severe generalized disturb

FIGURE 6 Case 6

Each of these two sets of electroencephalograms was made from frontal parietal and occipital leads, placed from above downward A, twenty days after the injury and B, five months after the injury. The time intervals are one second apart. In B, traces of 2 second and 3 second waves are still seen.

invalided permanently unfit (This case has been reported fully, with electroencephalographic records, by Williams¹¹). The electroencephalogram still showed traces of slow waves at 3 to 8 per second after 5 months (Fig. 6).

The ultimate breakdown in this case was clearly psychoneurotic and was conditioned by anxiety about the future. Nevertheless, it must be admitted that a certain degree of impairment of judgment could still be demonstrated by careful tests, that the patient always had been a poor scholar, although his family and personal histories were otherwise good, and that such intellectual impairment as directly resulted from the injury may in fact have been the only cause of the failure to attain an already limited adaptation to army life.

One may contrast patients who suffered comparable direct cerebral gunshot injuries, both perhaps with some slight residual disability, and whereas one made an excellent recovery, the other was held back by general post traumatic symptoms. The failure of the second was regularly traceable

ance; and a history of liability to psychoneurosis or failure in adaptation in the personality or family history. In this group also fall the morons and chronic psychopaths whose capacity for adaptation is already limited.

(To be concluded)

ACUTE PERFORATION OF ULCERS OF THE STOMACH AND DUODENUM

CAPTAIN HOWARD ULFELDER, M.C., A.U.S.,* AND ARTHUR W. ALLEN, M.D.†

RICHARDSON¹ reviewed the subject of acute perforation of ulcers of the stomach and duodenum from the data available at the Massachusetts General Hospital up to 1916. It is our purpose to present a study of the records of such patients from that date up to and including the year 1940. Richardson reported 103 cases with a mortality rate of 44.2 per cent. At the time of his writing, it was evident that the diagnosis was rarely difficult and that the best immediate results were obtained by simple closure of the perforation. There was at this time, however, a definite predilection for concomitant gastrojejunostomy in the good-risk patient. Moreover, the methods used for removing the extravasated fluid from the abdomen were variable. These technical differences persisted to some extent through the next decade. The last three five-year periods under discussion in our presentation, however, are comparable on the basis of the technic used, and were almost completed by the time the use of the sulfonamides had become common practice.

In the twenty-five-year period from 1916 to 1940, there were 334 admissions to our clinic with acute perforation of an ulcer of the stomach or duodenum. The diagnosis in all but 4 of these cases was confirmed at operation or autopsy. In one of the 4 exceptions the patient entered the hospital moribund, with a history and physical examination consistent with long-standing ulcer and acute perforation of thirty-four hours' duration. Operation was not performed and autopsy was unobtainable.

The other 3 patients survived without operation, and all the cases fulfilled the following criteria: history compatible with recent perforation; physical signs on admission consistent with peritonitis, free air under the diaphragm demonstrable by roentgenogram; and ulcer shown by a subsequent barium meal.

Only 13 patients, or less than 4 per cent of the entire group, were women. This ratio of 1:25 is interesting, since the sex ratio of ulcer in general is approximately 1:6. In fact, the proportion of women with ulcer who meet with the complication of perforation is somewhat in accordance with the peculiar protection they seem to possess from fatal hemorrhage from ulcer.² The incidence of the other chief surgical complication of ulcer—namely, cicatricial obstruction—is more nearly equal in men and women. It has been suggested that gastric ulceration in women is more apt to be benign than it is in men. Although our figures are not large enough to assure us of this fact, we are inclined to believe that it is not true, but that the same suspicion regarding malignancy should be held in both sexes.³ Six of the female cases of perforation were duodenal and 6 were gastric; 1 patient recovered without operation. Although there were 5 deaths in these 13 cases, the group is so small that we can only surmise that acute perforation of ulcer in women, although much rarer than it is in men, may, when it occurs, be more hazardous.

Considering only the 321 male cases in our series, we can divide them according to location of the ulcer as shown in Table 1. This would seem to indicate that the risk from perforation of an

*Assistant in surgery, Massachusetts General Hospital (on leave of absence)

†Chief East Surgical Service, Massachusetts General Hospital; lecturer on surgery, Harvard Medical School

ulcer proximal to the pylorus is slightly greater than if it occurs in the duodenum. Although these figures must encompass a definite slight error, owing to the operator's inability to determine invariably the exact location of the ulcer, the ratio of

gastric to duodenal in this group is nevertheless comparable to that found in our clinic for other complications of ulcer.⁴

Nine patients in the entire group had already survived a previous perforation. Strangely enough, all these recovered from the second episode. It is unlikely that this was merely coincidence; more probably the patient, recognizing a recurrence of his former symptoms, delayed less in obtaining treatment. Doubtless he called attention to his previous condition and made it easier for his physicians to make the diagnosis; thus the all-important time factor was utilized to his advantage.

Often the question arises regarding the proper treatment for the patient who has recovered from acute perforation. How persistently should palliative management be carried out after perforation? Should such a patient be subjected to a radical operation if symptoms persist or if conditions are such that proper self-care is unlikely? The danger of a second perforation has often been raised. It is, of course, impossible to make any blanket rule covering the situation; we do believe, however, that patients recovering from perforation should be carefully followed and the same principles of good ulcer management carried out as in those who have not suffered this complication. If the response to conservative treatment is satisfactory, there is no reason to classify them in a separate category. In fact, such patients are probably no more likely to be invalidated by their malady than is the average ulcer patient. If the complication of cicatricial stenosis, massive hemorrhage or intractability does occur, then surgery is justifiable.⁵

There was 1 case in which simultaneous perforation of more than one ulcer apparently occurred. This was unrecognized at operation, and the patient succumbed to peritonitis. Such a possibility is unlikely, and it may reasonably be suspected that the second ulcer perforated during the convalescence following the suture of the first.

Certainly there is no way to foresee such a complication, and this incident does not warrant extensive exploration to avoid overlooking a double perforation. The dangers of too much handling of tissues, under these circumstances, far outweigh the risk of overlooking a second perforation.

If our series is divided into its component five-year periods, as shown in Table 2, it is apparent that as early as 1920 the results of treatment became stabilized. It is also obvious, in spite of the elimination of drainage, concomitant gastroenterostomy and so forth, as well as the marked improvement in anesthesia, fluid balance, blood chemistry and other preoperative and postoperative adjuncts, that there has been a striking failure in lowering the mortality rate. Since an increasing

1936-1940	91	24	26.4

number of perforated ulcer patients have been treated in our clinic in the last three five-year periods, with a variation in mortality of less than 0.5 per cent, we have further analyzed this group of 255 patients to see whether any light can be thrown on the problem.

In Table 3, we have regrouped these cases according to the season of the year in which they occurred. Thus, it appears that during the winter

TABLE 3. *Incidence and Mortality according to Seasons (255 Cases).*

SEASON	NO. OF CASES	NO. OF DEATHS	MORTALITY %
Winter	59	22	37.3
Spring	64	17	26.8
Summer	56	13	23.2
Autumn	76	16	21.0

months the mortality is highest, while during the autumn it is definitely at its lowest point. In an effort to account for this variation, we have plotted in Figure 1 the curves of yearly death rates from acute respiratory-tract infection in Massachusetts and of the mortality rates from perforated peptic ulcer in our clinic. Although these curves are scarcely comparable, it is obvious that they tend to parallel each other, particularly in that no peak in the former curve is without its counterpart in the latter. The sharp drop in both curves in 1940 is doubtless due to the universal use of

sulfonamides. It appears, therefore, that there is some relation between the mortality rate for perforated ulcer in our clinic and the virulence of the current respiratory-tract infection in the community. In support of this hypothesis are the ob-

FIGURE 1. Comparison of Pneumonia Deaths and Operative Mortality in Cases of Perforated Ulcer.

The upper curve shows the deaths from pneumonia per 100,000 population in Massachusetts; the lower curve shows the corresponding percentage mortality rates in cases of perforated ulcer at the Massachusetts General Hospital.

servations of Griswold and Antoncic,⁶ DeBakey⁷ and Henry⁸ that denizens of the respiratory tract are by far the commonest pathogenic organisms cultured from the peritoneal fluid in these cases. Our own bacteriologic studies are in accord with these observers. In 47 cultures reported positive, 38 showed either pneumococcus or streptococcus; 34 per cent of these patients died, while only 7 per cent of those whose peritoneal cultures were reported as negative succumbed after closure of their perforation. It is in this group with positive cultures of virulent organisms that more modern methods of treatment by chemotherapy are apt to be effective. It will be surprising if the next report from our clinic on this subject fails to show a substantial decrease in the mortality rate.

Diagnosis in our group was rarely difficult. The history of previous indigestion is of importance, but there were a number of perforated ulcers in patients who had never been aware of any digestive disorders. Doubtless a better understanding regarding the so-called "silent" or painless area present in the duodenum of a great many people will lead to prompter diagnosis and treatment in such cases. The suddenness of the onset, with shock producing pain, localized in the epigastrium, should challenge every physician to suspect the diagnosis until disproved. Too often the onset of perforation is confused with gallstone colic, acute indigestion or angina, and the admis-

sion of the patient to a hospital is delayed for a dangerous period. In the hospital, moreover, time is often wasted in getting an x-ray examination. That free air within the abdomen can be demonstrated in a large percentage of such cases has been shown in our own series, with an incidence of 72 per cent. This doubtless could be improved on by keeping the patient in an upright position for several minutes prior to the examination or by using the method of Williams and Hartzell,⁹ who advise a lateral position for x-ray examination. Our own experience has convinced us that this confirmatory evidence is seldom necessary, and we are certain that much valuable time can be lost by laying undue stress on this method of diagnosis.

Figure 2 indicates diagrammatically the incidence and mortality according to the age of the patient. A comparison with similar data^{6,7} for other series reveals a tendency for our group to contain a larger proportion of older patients. Thus, 35 per cent of our patients had passed their fiftieth birthday, whereas most other series give figures of 18

FIGURE 2. Incidences of Cases and of Deaths according to the Age of the Patient.

to 23 per cent for this subdivision. Coupled with the consideration that the mortality in these ranges is well over 35 per cent, this fact must play a significant role in the statistics for the group as a whole. Indeed, 70 per cent of all our fatalities were in the older age group. Still further causes for delay in diagnosis are met with in the patients of advanced age, since it is here that the need for excluding coronary occlusion and acute pancreatitis arises in all upper-abdominal disturbances. The time element is so important that exploratory incision under novocain should be made in cases of doubt, in preference to waiting until the diagnosis is clear.

Surgeons unanimously agree that the time interval between perforation and closure outweighs all other factors in influencing the mortality. This interval could be accurately determined in 160 of our cases and is graphically presented in Figure 3. Although at first glance it appears that a

FIGURE 3 Incidences of Cases and of Deaths according to Elapsed Time between Perforation and Operation

gratifying preponderance of patients came to operation within the first twelve hours of their disease, actually the situation is much more urgent than that, for the curve of mortality with respect to elapsed time (Fig 4) shows its most rapid rise between three and six hours after perforation.

Sixteen patients came to operation between fifteen and thirty-three hours after perforation

FIGURE 4 Mortality Rate according to Elapsed Time between Perforation and Operation

Nine survived, but it is of interest that those who did so had either chemotherapy (2 cases) or specific mention in the operative note that the per-

foration was found already sealed off—with one exception, a patient who had a perforation described by the surgeon as 'pin point in size'.

Twenty-five patients not shown in Figure 3 were either not operated on or came to operation forty-eight hours after perforation. Of these, 8 survived, and in all the perforation had already sealed spontaneously, as demonstrated at operation (5 cases) or by the fact that they survived without surgery (3 cases). It is probably not mere chance that no case of ours was subjected to operation between the thirty-third and forty-eighth hours after perforation. It is more reasonable to assume that spontaneous sealing, if it is to occur at all, has most frequently taken effect by twelve to fifteen hours after perforation. Patients who escape surgery until the latter part of the second day will then fall into three categories: those in whom the perforation has sealed and the improvement has been sufficient to warrant conservative treatment, those who have full blown progressive peritonitis, in whom surgery is out of the question, and those in whom the earlier peritonitis has become localized and obstruction or abscess is developing.

DISCUSSION

Patients suspected of having acute perforation of the stomach or duodenum should be hospitalized at once, and exploration should follow confirmation of the diagnosis with the least possible delay. Acute perforation ranks as an emergency second only to cessation of respiration and massive hemorrhage. A delay of only a few minutes need be expended in passing the indwelling gastric tube and starting intravenous fluid. Roentgenologic and other diagnostic aids should be reserved for those cases in which the findings will influence the decision whether or not to explore. The diagnosis that in the recent past has most frequently caused delay in prompt operative treatment is acute pancreatitis. Diagnostic peritoneal aspiration to determine the character of the free fluid, or even a short exploratory incision under novocain, is undoubtedly a safer and surer method of resolving this difficulty than any amount of observation and supportive treatment.

We agree with Wangenstein¹⁰ that cases seen twelve hours after onset should be examined with particular attention for signs of localization, and evaluated with reference to possible nonoperative treatment—leaning more to this course in the older age group. In the final analysis, surgery is little to offer except mechanical closure of the perforation, and should the patient be fortunate enough for this to have been accomplished spontaneously, his chances of recovery are undoubtedly

better without the added burden of anesthesia and operation. This procedure fails to consider the possibility of leakage at the site of spontaneous closure, an accident occasionally mentioned in the literature. Any estimate on the chances of this complication must await the accumulation of more data than are now at hand. With the patient on constant gastric suction and Ochsner's regimen, however, it appears to us theoretically possible to reduce the incidence of this accident to a minimum.

Anesthesia should be varied according to conditions. Proper use of local or spinal anesthesia may be advantageous. Gastric intubation and suction should precede all anesthesia, particularly if by an inhalation method. At operation, the simplest means of effecting closure is the most desirable one. This may be done by sutures in small perforations or by an omental tab held loosely over the opening as described by Graham.¹¹ Routine culture of the abdominal fluid should be taken and as much free fluid removed as can be reached with a gently manipulated suction tip, particular attention being paid to the pelvis and subdiaphragmatic spaces. Drainage of the abdominal cavity is contraindicated.

On the basis of the findings of this study, we believe that failure to use any therapeutic agent that has demonstrated its value in the treatment of respiratory-tract infections is a serious omission. Indeed, reports⁶ have already appeared describing the use of chemotherapy locally and parenterally in this disease. The postoperative use of sulfonamide compounds may be directed intelligently on the basis of the peritoneal cultures.

Postoperatively, the stomach should be kept on constant aspiration until it is apparent that there is no leakage at the point of closure, also until it is obvious that secretions meet no obstruction in the pylorus or duodenum, and until there is re-establishment of the normal peristaltic function. Parenteral fluids, vitamins, blood or plasma should be administered as indicated. The use of morphine to retain small-bowel tone is essential but

should be tempered with wisdom, lest secretions be allowed to collect in the lungs and bronchi. Tracheal aspiration, as described by Haight and Ransom,¹² should be used at once to remove troublesome bronchial exudate that the patient is unable to expectorate.

SUMMARY

Three hundred and thirty-four cases of acute perforation of gastric or duodenal ulcer were seen at the Massachusetts General Hospital in the years 1916 to 1940, inclusive.

The mortality by five-year periods shows no significant change during the past fifteen years.

The mortality during the winter months is appreciably higher than during the other seasons.

There appears to be some relation between this mortality and the virulence of current respiratory-tract infection.

The mortality rises with the patient's age.

The interval between perforation and closure is of fundamental prognostic importance.

In the majority of patients who recovered when more than fifteen hours had elapsed between onset and operation, their perforation had already spontaneously sealed.

PAROXYSMAL TACHYCARDIA IN PREGNANCY

HENRY WEYLER, M.D.,* AND CECIL C. DUSTIN, M.D.†

PROVIDENCE, RHODE ISLAND

THERE has been some disagreement concerning the incidence of paroxysmal tachycardia in obstetric cases, and the true incidence is uncertain. Hamilton and Thompson¹ found it in 13 out of 781 patients with chronic rheumatic heart disease. However, they believe that it is found frequently during pregnancy in women who other-

The case we are presenting is of special interest because of the apparent five-year duration of the paroxysms of tachycardia, during which time the patient delivered four babies.

CASE REPORT

Mrs. A. H., a 24-year-old white woman, was under observation at the Providence Lying in Hospital during the

FIGURE 1. *Electrocardiogram Taken Two Months before Delivery.*

wise have sound hearts. Jensen² quotes a number of authors to indicate the conflicting opinions concerning the incidence of this condition. He concludes by saying that 19 cases have been recorded in such a manner as to leave the diagnosis beyond reasonable doubt. Eight of these had valvular disease, while 11 showed no evidence of heart disease. Browning and Clark³ described 2 more cases and published the electrocardiograms.

The latter part of four pregnancies. She had her first child on October 22, 1936, at the age of 19 years, and her last on November 30, 1941. During these pregnancies she was followed for 3 months, 5 months, 3 months and 3 months, respectively. Whenever she was examined throughout these periods she had short runs of tachycardia, interrupted by 1 to 4 slow beats. These findings were consistent with electrocardiograms taken during her first and last pregnancies. Throughout the past 5 years she had neither been conscious of any irregularity of the heart rhythm, nor had she had any discomfort.

The past history was negative except for measles and mumps at the age of 11 years and a tonsillectomy and adenoidectomy for prophylactic reasons at the age of 5.

*Assistant visiting physician, Rhode Island Hospital, assistant cardiologist, Providence Lying in Hospital.

†Visiting physician and assistant director of the Cardiac Department Rhode Island Hospital, chief cardiologist, Providence Lying in Hospital

In particular, there was no history of rheumatic fever, chorea or sore throat. There had been no symptoms associated with hyperthyroid activity.

Physical examination showed no evidence of heart disease. A Grade 2* systolic murmur, heard during the slow

point is evident in some of the other leads, but to a lesser degree.

In the electrocardiograms made 6 weeks after the last delivery (Fig. 2) there are no runs of tachycardia. The arrhythmia is due to ectopic beats that vary considerably

FIGURE 2. *Electrocardiogram Taken Six Weeks after Delivery.*
Note the ectopic beats in Lead 3.

beats and noted at the time of her first admission, persisted. The thyroid gland was not enlarged. The blood pressure ranged during the 5-year period from 110/69 to 122/86.

The usual laboratory findings were normal. The blood Wassermann reaction and urinalysis were negative. An x-ray examination of the heart on January 13, 1942, showed no enlargement. There was slight shifting of the heart due to scoliosis.

The electrocardiograms (Fig. 1) show a very interesting and unusual type of arrhythmia, characterized by short runs of paroxysmal tachycardia. These start with an ectopic beat and have a pause immediately following the spontaneous termination. The first complex following a run of tachycardia presumably represents the normal for the patient. In the record made before delivery, there are no places where more than two normal complexes occur in sequence. More often the slower rhythm is a coupling of a normal beat with an auricular ectopic beat. In the portions of the record showing normal complexes the rate is 64 per minute. The coupling has a rate averaging 94 per minute, and the runs of tachycardia average 140 per minute. There is only a slight variation in rate whenever the tachycardia is present.

For the most part there is very little difference in the PR interval time regardless of the type of P wave. It is evident in some of the tracings, particularly in Lead 1, that the last complex in the runs of tachycardia has a different shape of P wave than have the immediately preceding complexes. It seems that a shift in the origin of the impulse breaks up the run of tachycardia. This

in the point of origin. Some of these beats are definitely auricular, apparently arising near the sinoauricular node. Others are of a very different pattern, and are followed by ventricular complexes wholly unlike the normal. Lead 3 best illustrates this point. Some of the P waves are inverted, showing almost no change in the PR time as compared with the normal. These complexes have a ventricular response exactly like the normal. Other P waves are high and pointed, followed by ventricular complexes of a pattern usually associated with those arising in the ventricle. These odd complexes show a PR time that is within normal limits and almost identical with that of the normal beats. The ventricular response obviously does not follow the normal sequence.

This unusual irregularity of heart action known to have been present in this patient since her first pregnancy in 1936 has in no way interfered with her normal activity.

Attempts to control the tachycardia were unsuccessful. Small doses of digitalis were given during the last few weeks of the third pregnancy, without any effect. During the last pregnancy the patient was well digitalized, without any change in the rate or rhythm of the heart. After delivery she was given 3 gr. of quinidine sulfate[†] every 2 hours for thirteen doses. This was stopped because she complained of nausea. The electrocardiograms taken after the last dose showed a change in the pattern of the ectopic beats, with more coupling of normal and ectopic beats followed by longer runs of auricular tachycardia. The pa-

[†]Quinidine sulfate was considered during pregnancy but was not used until after delivery because we did not know its action on the uterus. There seems to be some reason for believing that the drug acts on the uterus only during labor. Browning and Clark² employed it during pregnancy and quote some authors recommending its use.

*Classification — Grades 1 to 6, according to loudness.

tient was discharged from the hospital on 3 gr. of quinine sulfate three times a day, but neglected to take it.

SUMMARY

A case of paroxysmal auricular tachycardia seen throughout the latter part of four pregnancies over a five-year period is reported.

GOVERNOR'S ADDRESS*

ROBERT O. BLOOD, M.D.†

CONCORD, NEW HAMPSHIRE

WE ARE met here tonight at a time when more people are being maimed in the world than at any other period in its history. We had a world war once that we now call World War I, but that was only a dress rehearsal for the present conflict.

Men in the medical profession have a greater job to do the world over than has ever befallen any generation of medical practitioners in our time or in the world's history. I am sure that physicians will find themselves equal to this task, as they have in all their trials in the past years of civilized history.

We here in this state have a real job to do, and in my dual capacity—practicing medicine and at the same time being the chief executive charged by the people with the administration of the state business as a whole—perhaps I feel a little greater responsibility because of my medical background and training as it relates to medical care than a layman would in my position.

We, the State, are spending a tremendous amount of money in medical care, both as it relates to prevention and control of disease and to the care of those who are diseased. Last year we spent almost \$1,300,000 for other than the institutional care of patients. For cancer patients the State spent the sum of \$43,000, and the total expended by the Cancer Commission was over \$58,000. The State Hospital spent the sum of \$866,000 last year for the care of patients. And I may say that Dr. Dolloff, your retiring president, is running an excellent institution and that the patients are well cared for; also, the State is in a better position by having them segregated there than it would be if they were scattered about. Over 2300 patients are there now, and it is hard to predict where the care of those with mental diseases will end. The situation is a little more hopeful as it relates to tuberculosis, where we are one of the lowest nine

states in deaths per 100,000 in a year. Our rate has gone constantly down for the last twenty-odd years. However, we still annually spend the sum of \$175,000 for the care of patients in the institutions at Glenclyff and Pembroke.

If you add together all the sums I have mentioned, you will see that for the care of people in institutions, for medical care as it relates to prevention, control and so forth, we are spending a very considerable amount of money.

I believe that the medical profession is somewhat derelict in its duty in not contributing more in personnel to the legislative halls of this and other states. You have no right, unless you participate actively in the control of the legislation that is passed, to expect a layman to do too good a job. So may I leave an appeal that some of you who can go to the Legislature do so and lend a little medical influence there? It isn't a very hard job.

I want to pay my respects to the medical legislation that you have received from our legislature. I believe—and I think you will agree with me if you look over the laws as they relate to medical care, sanitary regulations and so forth—that this state will rank high among the states of the country. Changes continue to be necessary. Public health and the Board of Health activities have grown so rapidly that changes are always necessary. I told you last year that the original law, passed in 1887, said that there never should be in any one year expended for health activities more than \$3000. But from that period we have grown, slowly at first, but recently very rapidly, and the result is what you would expect it to be; we have added function after function to our health activities, and we have never "sugared them off." Re-vamping is as necessary in the State's business as it is in any other business where you add functions, one on top of another.

The medical profession might well consider learning something about our state institutions—

*An address delivered at the annual banquet of the New Hampshire Medical Society, Manchester, May 13, 1942.

†Governor of New Hampshire.

where our people who are physically and mentally ill are housed — by visiting these institutions once in a while and seeing what is being done. I think it would surprise you if you asked the men here how many of them had visited Glenclyff, Pembroke, the Laconia School and the State Hospital.

We also have a large responsibility in molding public opinion. You men have been privileged — or you could not be practicing medicine — to obtain a college education. You are marked men because of your training, and because of that, you have increased obligations with the privileges and training that you have received. There never has been a time in this state when we needed more for purposes of morale, and for purposes of as-

sistance in many ways, leadership like the leadership that you men can give in your communities.

The federal government is, of necessity, — and, we hope, wisely, — making regulations that affect every one of us. So long as those regulations are there, and so long as those regulations are fair to all of us, no one in this state will hesitate to carry on as he should.

In this war, you and I and every last one of us have a job to do, and we will contribute, we must contribute, cost what it will, — you and I in this state and the people the world over in the United Nations will contribute, — all that is necessary to defeat the Axis; for much as it costs, it will cost much less to win a war than to lose one.

MEDICAL PROGRESS

PHARMACOLOGY AND PHARMACOTHERAPY*

HARRY B. FRIEDGOOD, M.D.†

BOSTON

IN RECOUNTING strategic advances in any branch of medicine, one must take into consideration not only the new discoveries of importance, but also the welfare and aims of the field in general. Both of these depend heavily on the stimulus and guidance of men of vision who reaffirm established principles, discover new ones and adapt all of them to the ever-changing conditions of each succeeding era. Pharmacology is a science that is traditionally devoted to the study of drugs and their effects on the animal organism; but the responsibilities and interests of the pharmacologist do not end there. His ultimate concern is with the therapeutic application of the drugs whose effects he observes experimentally. Although this viewpoint enjoys universal recognition, it has not always been possible to accomplish its aim, principally because there has been altogether too infrequent professional collaboration between pharmacologist and clinician. Fortunately, there have been an increasing number of such arrangements in more recent years. In the recent passing of Dr. Soma Weiss, pharmacology has lost the genius of an internist who saw the problem of pharmacotherapy in its broadest aspects, and who contributed to it in an outstanding fashion.

Modern trends in the development of medicine leave no doubt that the field of the pharmacologist includes not only a limited study of the effects of drugs, but encompasses also an increasingly large area of the neighboring sciences of bacteriology, immunology, physiology, histoanatomy and so forth. This review, although limited in its scope, pays tribute to this important conception by including references to representative investigations in some of these fields, which meet on the common ground of pharmacotherapy.

CHEMOTHERAPY

It is scarcely possible to exaggerate the importance of the continuing advances in chemotherapy. The spotlight of interest previously monopolized by the sulfonamides is being shared more recently with reports of the bactericidal activity of gramicidin and penicillin, and with further observations on massive-dose drug therapy in early syphilis. So far as the sulfonamides are concerned, a survey of the past year's publications indicates that the topics of major interest are as follows: mode of action; use in local therapy of burns, penetrating wounds of joints, compound fractures, ophthalmologic conditions (trachoma) and cutaneous infections; prophylactic implantation of sulfanilamide in clean operative wounds; and new derivatives, principally sulfasuxidine.

Kohn and Harris^{1, 2} have studied quantitatively the growth and respiration of *Escherichia coli* in

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress: Annals*, Vol. III, 1942 (Springfield, Illinois: Charles C Thomas Company, 1942. \$5.00).

*From the Medical Clinic, Peter Bent Brigham Hospital, and the Department of Medicine, Harvard Medical School, Boston.

†Instructor in medicine, Harvard Medical School; associate in medicine, Peter Bent Brigham Hospital.

different mediums in the presence and absence of the sulfonamides. At the bacteriostatically active concentrations studied, the sulfonamides do not inhibit respiration of the resting or growing organism. Kohn and Harris conclude that certain substances essential to growth and multiplication are stored in the cell, and that the rate of their synthesis is inhibited by sulfonamides.

Richardson³ has investigated the small Heinz bodies, which appear within twenty-four hours after the beginning of sulfanilamide therapy in the majority of mature red blood cells. He has found that these increase in size until they reach their largest diameter by the fourth or fifth day, when blood destruction is at its peak. The occurrence of these bodies is independent of the presence or absence of changed pigment, and preliminary analyses show that they are made up of considerable amounts of cholesterol and protein and very little iron.

The idea of employing sulfonamides in the treatment of local infections and for prophylactic purposes in surgery logically follows in the wake of its successful use in systemic infections, and represents one of the major recent achievements in this field. Hooker and Lam⁴ report the successful local use of sulfanilamide powder in extensive burns, which healed rapidly and uneventfully. They were particularly impressed by the rapidity of absorption of the powder from the burned surfaces and the high blood levels that were consequently induced. Key and Burford,⁵ Long and Dees⁶ and Bickford⁷ found sulfanilamide powder highly effective in the prevention of infections in compound fractures, crushing and lacerated wounds and penetrating wounds of joints. Key and Burford⁸ and Long and Dees⁶ emphasize the prophylactic value of sulfanilamide powder locally in clean operative wounds⁹ and in any gastrointestinal surgery with soiling of the peritoneum.⁶

Keeney, Pembroke, Chatard and Ziegler¹ advocate the use of a 5 per cent sulfathiazole ointment in the treatment of cutaneous infections on the basis of a study in 69 patients with infected infantile and adult eczema, seborrheic dermatitis, impetigo, acne vulgaris, bacterial folliculitis and furunculosis. Toxic effects were not observed.

Cosgrove and Hundley¹⁰ have continued the studies of Loe,¹¹ who first reported the successful treatment of trachoma with sulfanilamide. They too are impressed with the efficacy of local therapy, and report the cure of 83 per cent of patients in the first and second stages of trachoma.¹² They also found such local therapy efficacious in gonorrheal ophthalmia, pneumococcal conjunctivitis and post-traumatic corneal ulcers.

Most recently studied of the newer sulfonamide derivatives is succinyl sulfathiazole (sulfisuxidine). It was synthesized by Miller, Rock and Moore¹³ and subsequently studied clinically by Poth and Knotts¹⁴ and Matus and Welch.¹ Succinyl sulfathiazole exerts marked enteral bacteriostatic action, and the indications are that it will prove successful where sulfaguanidine has fallen short of its early promise. Pharmacologic studies in dogs and monkeys show that succinyl sulfathiazole administered orally has little toxicity and that it is poorly absorbed from the intestinal tract, so that only an average of 4 to 5 per cent of the ingested drug is excreted by the kidneys. Its action is essentially in the intestinal tract, as demonstrated by the reduction in the count of *E. coli* and the marked inhibition of anaerobic proteolytic bacteria, which causes the feces to become relatively odorless. Preliminary observations indicate that the dysentery bacilli, including the Shiga, Flexner and Sonne strains, are susceptible to its bactericidal action. This drug also promises to reduce greatly the hazards of intestinal surgery.

Dubos¹⁶ has opened a second front in man's fight against bacterial infection by starting with the conception that one can find in nature micro-organisms selectively adapted to the decomposition of almost every conceivable type of organic compound. He points out that like all living cells, micro-organisms carry out their biochemical functions by means of enzymes and catalysts, which can often be extracted in an active form from the bacterial cells that produce them. These catalysts show a remarkable specificity with reference to the type of reaction that they can bring about. With these considerations in mind, Dubos isolated from soil various new bacterial species that produce specific catalysts selectively adapted to protect experimental animals against certain bacterial infections. One of these agents (polysaccharidase), which is neither bacteriolytic nor bactericidal, acts by destroying the protective capsular material of pneumococci and thus renders them susceptible to the phagocytic action of the cells of the infected host. Dubos extracted the other protective agent, gramicidin, from a sporulating soil bacillus. Unlike the polysaccharidases, it does not belong to the class of enzymes, but must be regarded as a true antiseptic, minute concentrations of which inhibit the growth of susceptible species in nutrient mediums (bacteriostatic action), whereas higher concentrations actually kill bacteria (bactericidal effect). Gramicidin appears to interfere with some essential metabolic function of the invading micro-organisms. In this respect, the mechanism of its protective action presents some analogy with that of the sulfonamides. The bactericidal action of

gramicidin is in some way related to the staining characteristics of the bacterial cells. It does not affect gram-negative bacilli, and its action is apparently tied in with some as yet unidentified structural difference between gram-positive and negative cells. Dubos believes that it is not too much to hope that micro-organisms capable of attacking other types of pathogens or their toxic principles will eventually be discovered in nature.

In their experimental and clinical studies on gramicidin, Herrell and Heilman¹⁷ have observed that this substance has a powerful hemolytic effect, which renders its systemic use inadvisable. They recommend that it be used locally or in irrigating infected cavities that do not communicate with the blood stream. They used thyrothricin (the crude substance from which gramicidin is recovered) locally in the treatment of 12 cases of various types of infection with gram-positive bacteria and observed marked beneficial results in most cases without demonstrable damaging effects to the host's tissues.

The preparation of penicillin, an extract of a mold, opens a new and exciting chapter in the history of chemotherapy. An evaluation of the earliest reports on penicillin suggests that, if anything, it may have wider clinical application than gramicidin. Preliminary studies indicate that it can be given intravenously with impunity and that its use in the form of strong solutions is innocuous to tissue cells. Its bacteriostatic action in vitro resembles that of the sulfonamide drugs, with the following differences: the bacteriostatic action of penicillin against streptococci and staphylococci is much greater; the action of penicillin on these organisms, unlike that of the sulfonamides, is influenced to only a minor extent by the number of bacteria present; and in suppurating wounds, the bacteriostatic power of penicillin against these organisms, contrary to the sulfonamides, is not antagonized by hydrolytic protein breakdown products or products of tissue autolysis or pus.

The clinical experiments with penicillin are encouraging thus far, according to the report of Abraham and his co-workers.¹⁸ They administered penicillin intravenously to 6 patients with staphylococcal and streptococcal infections that had failed to respond to all previous therapy including the sulfonamides. Penicillin induced a fall in temperature and resulted in improvement of the local and general condition. The future appears to hold much that is good in store for gramicidin and penicillin and other substances of similar origin, not only from a chemotherapeutic viewpoint, but also because investigations that deal with the latter are bound to turn up collateral observations which should throw light on obscure phases of cellular

metabolism, enzyme chemistry, immunology and bacteriology.

Extensive studies on massive-dose therapy of early syphilis have been in progress for several years by virtue of a laudable co-operative experiment carried out under carefully controlled conditions in a number of widely separated hospitals. It was Ehrlich who first attempted to cure syphilis with massive doses of arsphenamine, but he abandoned the method because of unsatisfactory results. Chargin, Leifer and Hyman reintroduced the massive-dose procedure in the form of a slow intravenous drip with neoarsphenamine. The frequency of untoward reactions (especially peripheral neuritis) led them to substitute an arsenoxide, Mapharsen, for neoarsphenamine. Leifer, Chargin and Hyman¹⁹ report that 81 per cent of 334 patients with early syphilis were cured in five days by this method of treatment, and Elliott, Baehr, Shaffer, Usher and Lough²⁰ similarly found that 85 per cent of their patients in their series of 1600 cases were cured with identical therapy (1200 mg. of Mapharsen is the optimal total dose). Both groups of investigators encountered toxic encephalitis, which was a fatal complication in 0.3 per cent of the cases reported by Elliott et al. and caused cerebral symptoms without death in 1.1 per cent of the patients studied by Leifer et al. Encountered also were slight nausea, vomiting and diarrhea, which disappeared with the establishment of tolerance to the drug. Elliott and his co-workers found little evidence of liver damage and no renal damage, dermatitis exfoliativa, blood dyscrasias or nitritoid reactions in their 1600 treated cases. Although the results of these investigators are most promising, it would seem to be the better part of wisdom not to release their technic to the general practitioner until more work is done under controlled conditions with particular reference to the toxic arsenical encephalitis.

CARDIORENAL DRUGS

The bioassay of digitalis is a perennial problem in pharmacology. This past year has been no exception in this regard. Gold, Cattell, Kwit and Kramer²¹ point out that contrary to general expectation, current official methods for the standardization of digitalis do not ensure uniform potency of the drug, because the *U.S.P.* frog method of assay is not applicable to the human being. Their experiments show that when the frog and cat methods give different values for the potency of a preparation, the figure obtained by the cat method applies to human beings, whereas that obtained by the frog method does not. They have found, furthermore, that specimens that deteriorate in po-

tency with aging, as judged by the frog method, are not found similarly wanting either by the cat method or on clinical trial in human beings. More recently they²² have described a method of assay by means of which the potency of digitalis preparations can be compared in human beings, using one and the same subject and thereby eliminating errors arising from individual differences in susceptibility. Batterman, Holman and DeGraff²³ differ with Gold and his co-workers on the value of the cat method. They have studied preparations that were identical in potency according to the cat method, but weaker or stronger so far as the desired clinical therapeutic effects were concerned. They suggest the use of a mixture of constant proportions of three crystalline glycosides (lanatosides A, B and C) isolated by Stoll and Kreis from *Digitalis lanata*. None of the three satisfies the criteria for an ideal digitalis preparation, but their correct combination results in a product of known chemical composition, which they believe compares favorably in its clinical effect with *D. purpurea*. This preparation is assayed by the gravimetric method, which reinsures greater accuracy and uniformity of dosage.

A new diuretic worthy of clinical consideration, judging from preliminary observations, is the mercurated allyl succinylurea with theophylline recently reported by Nuhfer, Mellish and Buchter.²⁴ The toxicity of this solution was compared with that of Salyrgan theophylline. Ninety per cent of the dogs that were given 10 mg. of mercury per kilogram in the form of the new diuretic survived, whereas the Salyrgan preparation was fatal to 90 per cent of the dogs treated with a corresponding dose of mercury. Neither drug affected the cardiac automaticity, nor did a serious change in blood pressure result from the administration of 532 mg. of mercury per kilogram. A marked diuretic response was elicited in dogs by the preparation of mercurated allyl succinylurea with theophylline. Preliminary studies with this preparation at the Peter Bent Brigham Hospital show that an excellent diuresis can be induced in edematous cardiac patients without evidence of toxicity.

BLOOD ANTICOAGULANTS

The problems concerned with the treatment of thrombosis and the prophylactic therapy against postoperative thrombosis have been in the foreground of pharmacotherapy for some time. Heparin was naturally the first substance to be used in studies of this type. Many papers dealing with this subject have appeared during the past year or so, and for the most part the results indicate that heparin has a place in the treatment

of thrombosis and in the prophylactic care of the postoperative condition. Its probable value in embolectomy and other kinds of blood-vessel surgery is apparently even greater (Lam,²⁵ Bauer,²⁶ Murray,²⁷ Rea,²⁸ Ravdin and Wood²⁹ and Crafoord and Jorpes³⁰). An extensive review of the development of this field can be found in an article by Jorpes.³¹ Heparin has disadvantages, however, that limit its clinical usefulness; for example, it is expensive, it is effective only when administered parenterally, and its activity is of relatively brief duration. A series of well-conceived, brilliant experiments by Campbell, Roberts, Smith, Link and Overman³²⁻³⁴ were instrumental in bringing to light a new anticoagulant,—3, 3'-methylenebis(4-hydroxycoumarin),—which prolongs coagulation and prothrombin time. Their work was based on a previously recognized hemorrhagic disease in cattle (sweet-clover disease), which was described independently by Schofield³⁵ and Roderick.³⁶ The isolation and crystallization of the hemorrhagic agent were finally accomplished last year by Campbell, Link, Stahmann and Huebner.³⁷⁻³⁹ Recent preliminary communications on the clinical application of the aforementioned discoveries by Meyer, Bingham and Axelrod⁴⁰ and Butt, Allen and Bollman⁴¹ give one the impression that this principle bids fair to replace heparin for most purposes. Obviously, a great deal of clinical experimentation under carefully controlled conditions must still be done in order to substantiate the early promise of this substance and the absence of toxicity. The work thus far indicates, however, that the preparation is nontoxic; it is effective when administered orally; furthermore, it has a longer action and is cheaper than heparin.

NARCOTIC PROBLEM

The narcotic problem has come in for its share of attention during the past year. Demerol, a new analgesic drug, has been studied for its properties of addiction, tolerance and clinical effectiveness with special reference to the possibility of substituting it for morphine. Himmelsbach⁴² found that the abstinence syndrome and withdrawal symptoms were typical of, but less severe than, those induced by morphine when Demerol was given to a group of post-addicts or "recovered" patients under controlled conditions. Andrews⁴³ has observed that the pain-threshold-raising effect of Demerol, as determined by the Hardy-Wolff method, is consistently reduced, and that tolerance to this drug is similar to, but less permanent than, that developed to morphine. Batterman⁴⁴ states that Demerol has proved to be a satisfactory and safe drug in over 800 patients, most of whom would have required morphine for the relief of pain.

Slaughter, Parsons and Munal⁴⁵ have observed that prostigmin potentiates the pain-relieving action of morphine. Their observation had its origin in the work of Slaughter and Gross,⁴⁶ who found that the two drugs were synergistic in their action on the intact dog's intestine and were strikingly similar in some of their cholinergic effects. Their work shows that $\frac{1}{8}$ gr. of morphine sulfate plus 1 cc. of prostigmin methyl sulfate (1:2000 solution) acts more rapidly and is more effective than $\frac{1}{4}$ gr. of morphine sulfate alone. Furthermore, the combination affords excellent preoperative and postoperative sedation and a decreased incidence of postoperative distention and urinary retention.

DILANTIN SODIUM IN EPILEPSY AND ASTHMA

An important contribution to the treatment of epilepsy (and possibly bronchial asthma) is to be found in Dilantin Sodium.⁴⁷⁻⁴⁹ This is a drug which, with little or no hypnotic effect, prevents or greatly decreases the frequency and severity of convulsive seizures in a majority of epileptics. It is said to be much more effective in the management of seizures of the psychomotor-equivalent variety than phenobarbital or bromides. Dilantin is not recommended for patients whose seizures occur only at long intervals, unless moderate doses of phenobarbital are ineffective or induce undesirable side reactions. The great majority of toxic reactions to Dilantin Sodium occur only when large doses are employed. The gastrointestinal symptoms are chiefly nausea and vomiting, while the central-nervous-system toxicity consists of nervousness, tremor of the hands, drowsiness, headache, and ataxia. Hypertrophy of the gums and a toxic dermatitis, varying from erythema to a severe morbilliform rash, are among other toxic effects observed. Another of the toxic manifestations to which attention is being directed is the rapid and progressive fall in the blood ascorbic acid level.⁴⁸ This factor has immediate clinical importance from several viewpoints, and awaits further elucidation and evaluation. Shulman⁵⁰ has used Dilantin Sodium in bronchial asthma with encouraging results. He was stimulated to try this drug in 7 young children because of the psychosomatic aspects of the so-called "asthmatic personality."

BELLADONNA AND SYNTROPAN

A controversy over the relative merits of *U.S.P.* and Bulgarian belladonna root seems to have been settled satisfactorily. A number of investigations were stimulated by the observations of Raeff, who claimed a distinct measure of superiority for the Bulgarian belladonna plant over others in the treatment of the distressing symptoms of post-encephalitic Parkinson's syndrome. Neither Price and Merritt⁵¹ nor Fabing and Zeligs⁵² were able

to confirm Raeff's work, although the latter believe that a white-wine extract of *U.S.P.* belladonna in desiccated form (that is, pressed into tablets) is preferable to the ordinary tincture because the latter is chemically unstable and subject to deterioration.

Obstetricians will be much interested in the observations of Stoll,⁵³ who has reported that Syntropan reduces the length of labor by half if it is given when dilatation of the cervix begins. It appears to be a safe and effective method for the shortening of labor, although the pharmacologic and physiologic aspects of its effects are still unknown. Stoll believes that its effect may be related to the drug's relaxing action on the lower uterine segment or cervix.

LIPOTROPIC SUBSTANCES

According to Best, Huntsman and Ridout,⁵⁴ a lipotropic substance is one that decreases the rate of deposition and accelerates the rate of removal of liver fat. The study of these substances had fallen almost entirely within the domain of the laboratory scientist until quite recently, when Dragstedt⁵⁵ brought it to the attention of clinicians. A number of lipotropic substances have already received careful study, including choline and betaine, methionine and cystine and inositol and lipocaic. From a clinical viewpoint, Dragstedt's studies of lipocaic render it of more immediate interest than any of the other lipotropic substances. The foundations for the interesting discoveries that have been made in this field were laid in 1924 by Allan, Bowie, Macleod and Robinson.⁵⁶ They reported that depancreatized dogs receiving adequate amounts of insulin and maintained on a diet of lean meat, sucrose and bone ash did not survive for periods longer than a few months. They also found that the addition of raw pancreas to the basal diet prevented the symptoms of failure of liver function that were due to fatty infiltration of the liver. They suggested, therefore, that the pancreas might produce an internal secretion necessary for the physiologic integrity of the liver. Somewhat later it was demonstrated that egg-yolk lecithin and choline (the active agent in lecithin) could prevent the accumulation of liver fat (Best, Hershey and Huntsman⁵⁷); and Best and Huntsman⁵⁸ also found that choline could restore to a normal fat content livers of rats that had been made fatty by a high fat diet. There is considerable controversy concerning the chemical nature of lipocaic and its relation to choline and inositol. For present purposes it is sufficient to point out that lipocaic may play an important role in diabetes mellitus and arteriosclerosis. Dragstedt⁵⁵ has pointed out that two types of fatty infiltration

of the liver occur in both diabetes mellitus and experimental pancreatic diabetes. One type is due to poor control of the diabetes by inadequate insulin therapy and is characterized by a normal or high concentration of the blood lipids and acidosis; it is relieved by proper insulin therapy. The second type is due to lipocaic deficiency and is characterized by a low concentration of the blood lipids, impaired liver function, decreased glucose tolerance and insulin sensitivity; it is relieved by lipocaic, but not by insulin. Lipocaic apparently prevents arteriosclerosis in depancreatized dogs, in which there is a greater incidence of this condition than is normal for this species. The implications of these studies are obvious when one recalls that diabetic patients are much more likely to develop presenile arteriosclerosis (coronary disease and peripheral arteriosclerosis with gangrene of the extremities) and that enlargement of the liver due to extensive fatty infiltration is not uncommon in human diabetes mellitus, particularly in children.

NUTRITIONAL ACHROMOTRICHIA

The field of vitamin therapy is too large to be included in a limited review of this type. One vitamin substance, however, which has been the subject of nation-wide publicity, merits a few words in passing. Ansbacher's⁵⁹ observations on the chromatrichial actions of *p*-aminobenzoic acid precipitated a controversy as to the nature of the gray hair factor or factors. Unna, Richards and Sampson⁶⁰ and Emerson⁶¹ were unable to attribute chromatrichial activity to *p*-aminobenzoic acid and held that pantothenic acid was the most likely source of this action. Such wide discrepancies suggested that some factor, unrecognized by either group, might be complicating the situation. With this in mind, Martin⁶² set up a series of well controlled dietary experiments on rats in which he found that six basic vitamin factors (B₁, B₂, B₆, choline, calcium pantothenate and nicotinic acid) are adequate for seemingly normal nutrition unless either *p*-aminobenzoic acid or inositol is added to the diet. He found that the addition of one of these two vitamins to the basic diet precipitated a deficiency of the other. He concluded therefore, that the *p*-aminobenzoic acid deficiency noted by Ansbacher⁵⁹ and Martin and Ansbacher⁶ was made possible by the inositol that was included in their basic diets. Neither Unna et al⁶⁰ nor Emerson⁶¹ had inositol in their basic diets, which accounts for the fact that they did not encounter a similar deficiency syndrome. Martin attributes this interdependence of vitamin substances to their effect on the bacterial growth in the gastrointestinal tract and hence on the bac-

terial synthesis of vitamin factors. Experiments such as Martin's serve to re-emphasize the complexity of the biochemistry and physiology of the vitamins. The study of these essential substances from a pharmacotherapeutic viewpoint is still more difficult because clinical experiments are less easily controlled than laboratory conditions. Martin's observations, which dovetail neatly with the experiences of other investigators, suggest that apparently innocuous chemical substances, such as vitamins, may in some circumstances induce undesirable repercussions in the body economy by upsetting what would otherwise be a biologic system in equilibrium. With this in mind, the administration of vitamin therapy to patients who show marked nutritional deficiencies should be approached with more caution than is customary, otherwise the injection or ingestion of large quantities of one or more vitamins can precipitate unrecognized subclinical deficiencies into major problems, to the great detriment of the patient. For these reasons, initial dosages are best kept within the physiologic range, and changes in metabolism should be induced gradually, not abruptly.

Martin's experiments and the experiences of other investigators indicate that there are various patterns of nutritional achromotrichia that are in some way related to the kind of vitamin deficiency that is present. This, coupled with the fact that the chromatrichial action of *p*-aminobenzoic acid is not based on simple biochemical and physiologic reactions, should put the clinician on guard against premature dogmatic conclusions with reference to any phase of this subject. In this reviewer's limited experience, there have been a few patients in whom *p*-aminobenzoic acid has shown chromatrichial activity under special circumstances; but there was also a case in which a combination of estrogen and progesterone restored prematurely gray hair of a lustrous silvery sheen to its original light brown color after several months of treatment. In this connection, the claims of Sieve⁶⁴ would seem injudicious, to say the least. With a minimum of published data, Sieve has credited *p*-aminobenzoic acid with a group of unique properties as a result of studying 800 patients in eight months. He states that this vitamin is clinically useful in a number of ways, among which are the following: it darkens gray hair; it intensifies the normal pigmentation of the nipples and mucous membranes of the mouth, vagina and anus, it eradicates areas of vitiligo; it induces a return of color and "changes the hypertrophy" of areas of leukoplakia in the mouth; it causes a decrease or almost complete disappearance of hyperpigmentation of nevi and freckles; it stimulates the libido, it re-establishes the menstrual cycle in amenorrhea

and increases the amount of flow in oligomenorrhea; it cures female sterility (12 out of 22 cases); it benefits asthmatic patients in certain instances; and it increases the appetite and induces a feeling of well-being. Although experimental laboratory evidence indicates that *p*-aminobenzoic acid is biologically active, the list of attributes that Sieve has ascribed to this chemical substance is formidable.

ENDOCRINE PHARMACOTHERAPY

Specific knowledge concerning the biochemistry and physiology of the male sex hormones is of comparatively recent date. Testosterone was synthesized in 1935 by Ruzicka et al.⁶⁵ and by Bute-nandt and Hanisch.⁶⁶ In 1936 it was reported that organic acid esters of testosterone, such as the propionate, were more active than testosterone. The most recent advance in this field has been the development of an orally effective androgen in the form of methyl testosterone.^{67, 68}

The androgens have become increasingly important in endocrine pharmacotherapy as a result of the availability of synthetically prepared organic acid esters of testosterone. A survey of the literature discloses that there are essentially three types of male sex hormone deficiency that have been treated successfully with these synthetic androgens: hypogonadism — this group includes castrates, eunuchs, eunuchoid individuals and others who exhibit only mild symptoms of androgenic deficiency; the male climacteric syndrome; and cryptorchid prepuberal boys.

There is a unanimity of opinion in the reports of investigators who have used testosterone propionate (parenteral) and methyl testosterone (oral) in the treatment of various types and degrees of hypogonadism. Vest and Howard⁶⁹ have reported on the effects of male sex hormone therapy in several hypogonadal men. Libido was restored to 3 of the 4 men who had emissions for the first time. In all 4 cases, the testes increased in size and all symptoms of hypogonadism were ameliorated. Miller, Hubert and Hamilton⁷⁰ treated 6 impotent patients under controlled conditions (2 castrates, 2 hypogonads and 2 patients in whom impotence was probably of psychic origin). The castrates regained normal potency and personality disorders appeared to be improved in the others. Among the 54 patients treated by Turner⁷¹ were cases of hypogonadism that responded to androgen therapy with an increase in the hair growth, the penile growth, the libido and the frequency of erections and emissions. The doses of testosterone propionate used by various investigators have ranged from 15 to 150 mg. per week. Byron and Katzen,⁷² Kearns,⁷³ McCullagh,⁷⁴ Mc-

Cullagh and Rossmiller,⁷⁵ Foss,⁷⁶ Eidelsberg and Madoff,⁷⁷ Escamilla and Lissner,⁷⁸ and Wilhelm⁷⁹ observed that methyl testosterone, orally administered, is highly efficacious in the treatment of the castration syndrome and severe or moderate instances of eunuchoidism. Simonson, Kearns and Enzer⁸⁰ have made special notes on the beneficial effects of androgen therapy on the fatigue of eunuchoids and castrates. The reports from various sources cited above state that the dose of orally administered methyl testosterone is from two to six times that of testosterone propionate if one is to achieve comparable results. It has been stated that the severity of the symptoms may determine in large part the dose necessary to control the syndrome. However, it has been the experience of this reviewer, in keeping with that of Kearns,⁷³ that the more outspoken the condition, the less androgen it takes to control it and the quicker amelioration of the hypogonadism occurs.

With but few exceptions there is apparently little realization of the potential value of the synthetic androgens in the treatment of the distressing symptoms of the male climacteric. This is due mainly to the attitude of a good many physicians who have been reluctant to recognize that the male climacteric is a clinical entity. A recent editorial in the *Journal of the American Medical Association* is an official expression of this skeptical viewpoint.⁸¹ Opinions to the contrary notwithstanding, there is increasing clinical evidence of a syndrome that one may properly term the "male climacteric." The condition occurs spontaneously in men, most frequently after their fortieth year and yields satisfactorily to androgen therapy if it is properly administered. This reviewer's experience, as yet unpublished, confirms the observations of others who have described this syndrome. The latter is characterized by a lack of mental, physical and sexual drive, and may not include significant impotence in the early stages. The varied symptoms of this condition are headache, emotional instability, a tendency to periods of depression, abnormal fatigue and lassitude, impairment of memory and inability to concentrate, insomnia and occasional symptoms of vasomotor instability. It has been a not uncommon experience to find that individuals suffering from this condition go from one physician's office to another because of what appear to be intangible complaints for which an organic basis cannot be found. They finally become tagged with descriptive symptomatic diagnoses such as psychoneurosis, hypochondriasis, headache of unknown origin and even involutional melancholia.

The literature on this subject is still relatively limited. Schmitz⁸² treated 45 cases of the male

climacteric and of impotence and noted improvement in 36 of them, Donald,⁸³ who reported on a series of 50 cases of the male climacteric found that the psychologic symptoms improved first and that there was a subsequent return of mental and physical vigor. Venzmer,⁸⁴ Monetti,⁸⁵ Wolbrist,⁸ Kearns⁷³ and Finkler and Cohn⁸⁷ have observed a fairly large series of patients who were treated with either parenteral or oral androgenic therapy. They observed considerable improvement (loss of impotence, re establishment of mental and physical energy, relief from headache and vertigo and so forth). The dosage of androgen used in the treatment of these patients varied considerably (from 15 to 150 mg of testosterone propionate per week). In this reviewer's experience, an adequate dosage has been 25 mg of testosterone propionate parenterally four times per week for four to six weeks, and 30 to 40 mg of methyl testosterone* orally daily thereafter. For the time being, the only diagnostic procedure is to keep the possibility in mind when a likely case is encountered and to subject the patient to a therapeutic test.

The use of testosterone esters in the treatment of cryptorchidism or infantile genitalia in boys of the Frohlich type constitutes a relatively new departure in endocrine therapy and should be engaged in under carefully controlled conditions. It was believed until recently, because of physiologic experiments, that the administration of testosterone induced atrophy of the testes although it stimulated the growth of the penis, scrotum, seminal vesicles and prostate as well as development of pubic and axillary hair. Shay and his co-workers⁸⁸ state, however, that under certain well defined conditions immature germinal epithelium can be stimulated by testosterone propionate to increased activity. They found that the testes of treated animals contained more mature spermatozoa than those of controls. Curiously enough, they observed also that large doses of testosterone propionate caused less inhibition of growth and sperm maturation than did small doses. Jaffe and Brockway⁸⁹ report that testosterone propionate and methyl testosterone influenced favorably the growth of infantile genitalia in 5 of 7 boys. They observed the descent of a testis in only 1 of 5 cases of cryptorchidism. They also noted the increase in size of one atrophic testis. Moller Christensen⁹⁰ favors chorionic gonadotropin for the treatment of cryptorchidism, but finds that a combination of the latter with testosterone is more effective. He found that boys from twelve to fourteen years of age responded most easily. Hamilton and Hubert⁹¹ report findings in 20 true cryptorchids

(8 bilateral, 12 unilateral) who were given testosterone propionate. The testes descended satisfactorily in the 8 bilateral cases, whereas the results were only partially successful in the 12 with unilateral retention. Zelson and Steinitz⁹² and Wilson⁹³ confirm the fact that bilateral cryptorchids respond to therapy with androgens more satisfactorily than do unilateral cases. Wilson reports that 30 per cent of his cases reacted satisfactorily, and Zelson and Steinitz⁹² found that 53 per cent of their cases were treated successfully with a combination of androgens and chorionic gonadotropin. Four of the 9 boys in their series had failed to respond previously to either one or the other of these preparations alone. The reviewer's unpublished experience with this form of therapy is encouraging thus far. Six cases of cryptorchidism or infantile genitalia in which chorionic gonadotropin had failed previously to elicit a favorable response, reacted strikingly to the administration of 10 to 12 mg of testosterone propionate three times per week or 10 to 20 mg methyl testosterone orally daily. The dose had to be adjusted in each case so that neither frequent priapism nor too rapid growth of the penis occurred, both of these are commonly encountered if too much hormone is given. The testes increased in size in every instance. In 1 case, which had responded only in differently to chorionic gonadotropin over a period of eight months, the combination of the latter with testosterone propionate resulted in a rapid growth of the external genitalia and the appearance of a palpable right testicle where none had been felt previously. Boys undergoing this treatment showed an increased rate of growth and tend to lose the Frohlich type of habitus (although it is possible that judicious dieting may play an important part in the latter result).

The androgens have been used in the treatment of peripheral vascular disease, angina pectoris and benign prostatic hypertrophy. Reports of such observations are still too few and too sketchy to warrant discussion in this review.

Certain gynecologic conditions have also been treated with androgens. Reports have appeared on its use in the menopausal syndrome, dysmenorrhea, premenstrual pain in the breasts, suppression of lactation and menometrorrhagia. Salmon,⁹⁴ Silberman, Radman and Abarbanel,⁹⁵ Nicholson and Towne⁹⁶ and Kurzrok, Birnberg and Livingston⁹⁷ have reported successful results in the treatment of the menopausal syndrome with testosterone propionate. Demarest,⁹⁸ Spence⁹⁹ and others have used the androgens for the relief of premenstrual pain in the breasts. Birnberg, Kurzrok and Klor,¹⁰⁰ Siegler and Silverstein¹⁰¹ and

*The Perandren and Metandren used in these experiments were kindly furnished by the Ciba Pharmaceutical Products Incorporated, S. M. New Jersey.

Beilly and Solomon¹⁰² have observed complete inhibition of lactation with this therapy. Rubinstein and Abarbanel,¹⁰³ Geist¹⁰⁴ and others have claimed a large measure of success in the use of androgens for the relief of dysmenorrhea. The androgens have apparently been used with success in the treatment of excessive bleeding due either to uncomplicated menorrhagia, metropathia hemorrhagica or uterine fibroids, according to the reports of a number of investigators including Loeser¹⁰⁵ and more recent ones by Sturgis, Abarbanel and Nader,¹⁰⁶ Huffman,¹⁰⁷ Greenhill and Freed¹⁰⁸ and Geist.¹⁰¹ There is considerable difference of opinion concerning the amount of testosterone propionate necessary to control so-called "functional bleeding" and the mechanism by means of which it is accomplished. Some believe that testosterone inhibits the gonadotropic activity of the pituitary and thus reduces the secretion of the ovarian hormones; others suggest that it suppresses the secretion of the ovarian hormones at their source; and it is also thought that this androgen may have a direct inhibitory effect on the intermittent rhythmic contractions of the uterine musculature, thus reducing the amount of blood flow through the uterus.

The use of androgens for the treatment of certain gynecologic endocrinopathies has not been fully justified by its protagonists to the satisfaction of most clinicians. From this reviewer's viewpoint, the best one can say for the use of testosterone in the treatment of the menopause is that it represents an interesting physiologic experiment, which may lead to information concerning the pharmacology, physiology and biochemistry of the androgens. There appears to be no justification, however, for its use clinically except in occasional cases of excessive uterine hemorrhage, because the female sex hormone is more easily obtainable, is less expensive, can be given without the risk of inducing masculinity, and is physiologically more appropriate than testosterone. As a matter of fact, it would be desirable to adopt a conservative attitude toward the use of androgens in the treatment of most of the gynecologic endocrinopathies until sufficient time has elapsed to permit a more dispassionate appraisal of the situation under controlled experimental conditions. The widespread clinical use of androgens for such purposes is to be discouraged at present, but there is little doubt that further study will more clearly define the indications for the physiologic significance of successful androgen therapy in gynecologic disorders.

Synthetic oral and parenteral preparations of progesterone are available for clinical therapy, but a perusal of the literature leaves one in some doubt about the clinical indications for its use. Theoretical-

ly, from a physiologic viewpoint, it should be helpful in a number of conditions, and on this basis it has been recommended for the treatment of recurrent and threatened abortion, functional menometrorrhagia, dysmenorrhea, amenorrhea, and premenstrual breast tenderness. Many articles have been published in support of the use of progesterone in each of these conditions, but a high percentage of them are not critical enough of the experimental conditions on the basis of which the conclusions are drawn. Take, for instance, the extensive literature on the use of progesterone in habitual or threatened abortion, much of which is reviewed by Kotz, Parker and Kaufman.¹⁰⁹ With the exception of Campbell and Sevringhaus,¹¹⁰ investigators of this phase of the subject, including Kotz and Parker, have claimed successful results with progesterone although they have routinely administered vitamin E and thyroid to each of their patients. The well-known salutary effects of each of these substances in habitual abortion are ignored for no apparent reason. Furthermore, the relatively small doses of 1 or 2 rabbit units of progesterone per week used by Campbell and Sevringhaus leave one wondering whether other factors did not have as much to do with the success they had in the handling of their cases. There is apparently no question that the percentage of patients who suffer from habitual or threatened abortion can be significantly decreased by an intelligent program that takes a number of pertinent factors into consideration, but to credit progesterone with each success would appear to be undesirable from a theoretical as well as a practical viewpoint.

Diethylstilbestrol, endocrine only through the courtesy of the physiologist, is a drug about which there is considerable controversy. It and the natural estrogens are not identical pharmacologically. Reynolds and Foster¹¹¹ have observed that even large doses of diethylstilbestrol do not cause an increase in the acetylcholine content of the uterus, whereas this does occur with the natural estrogens. In addition, DeWit and Bretschneider¹¹² have found that the drug does not cause the ovipositor reaction in female bitterlings, even when present in the water in lethal concentrations. Furthermore, diethylstilbestrol appears to be metabolized somewhat differently from the natural estrogens. The latter are largely destroyed in the liver, whereas the former is less affected by this organ and is eliminated to a much greater extent in the excreta, principally the urine (Zondek and Sulman¹¹³ and Stroud¹¹⁴).

Advocates of the relative harmlessness of diethylstilbestrol point with complacent satisfaction to the well-recognized fact that the nausea, vomit-

ing and dizziness of certain so called "sensitive persons" often disappear if therapy is continued in spite of these unpleasant symptoms. Forgotten is the additional fact that any toxic substance (for example, arsenic or nicotine) acts in a similar fashion. That is, a tolerance is built up that masks the objectively undesirable features of the drug. It should also be recalled that these toxic effects are induced by parenterally, as well as by orally, administered, stilbestrol. This indicates that the toxic effect is central. How much subtle damage (or lack of it) diethylstilbestrol may do over a period of years is as yet unknown, but in spite of this uncertainty too much of this drug is being prescribed without sufficient clinical indication just because it is relatively inexpensive and easy to obtain. Fortunately, the use of the natural estrogens has been curtailed for quite the opposite reasons.

* * *

A review such as the foregoing is necessarily limited by the author's experience as well as by the extensiveness of the field. Nor has any attempt been made to include a discussion of all the contributions to each of the subjects that has been entertained. It is to be hoped that many of the important advances have been accounted for

**CASE RECORDS OF THE
MASSACHUSETTS GENERAL HOSPITAL**ANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor***CASE 28471****PRESENTATION OF CASE**

A fifty-year-old machine-shop foreman was admitted to the hospital because of back pain.

Approximately three months prior to admission the patient noted occasional "twinges" of aching pain in the left lumbar region. He found that sitting slumped down in the chair afforded some relief. He also obtained moderate temporary relief from adequate doses of aspirin, which he had taken during the entire illness. The pains gradually became more frequent and severe. Nine weeks before entry, severe pains developed in the left sacroiliac region and radiated down the inner aspect of the left leg, two thirds of the way to the knee; these forced him to give up his work. He compared the pain to that of sciatica, with which he had suffered for several years. At times, however, the pain radiated into the left groin and left upper quadrant and around under the left shoulder. He slept sitting up, because he found that he had less pain in this position. There was no pain associated with bending of the trunk or flexion or extension of the legs. Three weeks prior to admission he entered a community hospital, where the x-ray studies were said to have demonstrated arthritis and a slight curvature of the spine in the lumbar region. He was fitted with a supporting belt, which was said to have afforded some relief. During the two weeks before entry he had a fever ranging between 100 and 102°F. and his ankles became swollen. During the previous nine months he was said to have lost 30 pounds and to have developed a slight degree of exertional dyspnea. His appetite was good until nine weeks prior to admission, when it fell off markedly. No abdominal discomfort occurred on a moderate diet, but when he overate he suffered with gas and sour eructations, which became progressively worse. At no time did nausea, vomiting or diarrhea develop. He had always been quite constipated, for which he took enemas or Sal Hepatica. No changes were noted in the color of the stools.

Physical examination revealed a thickset, slightly pale man who was wheezing and belching but who did not appear to be in real distress. The

heart was normal. Musical, dry rales and wheezes were audible throughout the chest. The abdomen was moderately distended and tympanitic. There were tenderness and spasm in the left upper quadrant, which prevented careful examination of a left upper-quadrant mass that descended with inspiration. At the left costovertebral angle there was slight tenderness. There was a right mid-dorsal kyphosis and scoliosis, but the spine was flexible and there was no limitation of motion. Several fairly large hemorrhoids were felt on rectal examination. The prostate was moderately enlarged, smooth, firm and symmetrical, and was not tender.

The blood pressure was 130 systolic, 80 diastolic. The temperature was 100.5°F., the pulse 110, and the respirations 30.

The examination of the blood revealed a hemoglobin of 12.8 gm. and a white-cell count of 16,300 with 87 per cent polymorphonuclears. The urine was acid in reaction, had a specific gravity of 1.015 and gave a + test for albumin; the sediment contained a rare hyaline cast, 1 red cell and 5 white cells per high-power field. These findings were unchanged on repeated examinations. The blood Hinton test was negative. A van den Bergh was too low to read. The blood nonprotein nitrogen was 22 mg. per 100 cc., the calcium 12.7 mg., the phosphorus 2.6 mg., the phosphatase 8.1 Bodansky units, and the protein 5.1 gm. (albumin 2.6 gm. and globulin 2.5 gm.). A stool examination was negative for blood and mucus. The spinal-fluid pressure was 130 mm. (water) and the fluid contained 5 cells per cubic millimeter; the protein was 18 mg. per 100 cc., and the Wassermann test was negative. A Widal test, a heterophile-antibody test and an agglutination test for undulant fever were negative.

In an x-ray film of the chest there was mottled density in the left lower lung field and there appeared to be some pleural thickening in the left costophrenic angle; otherwise the lung fields were clear. Fluoroscopically, the changes in the left lower lung field appeared to be due to atelectasis and impaired aeration as a result of the elevated left diaphragm, which showed limitation of motion. The heart was not definitely increased in size. X-ray films of the spine showed slight degenerative changes about the lower thoracic and lumbar vertebrae; otherwise there was no definite variation from the normal. In the gastrointestinal series only a small amount of barium was given because there appeared to be considerable gas in the bowel and the patient complained of rather severe constipation. The esophagus seemed normal. The mucosa of the stomach showed no definite evidence of ulceration, but there appeared to be pressure

on the posterior wall and lesser curvature from an extrinsic mass. The duodenal loop showed no definite evidence of a constant pressure defect except that the ligament of Treitz and the proximal loop of jejunum appeared to be displaced downward by the palpable mass in this region. The spleen was not definitely enlarged. In the intravenous pyelogram the kidney outlines were not well visualized. There was an area of calcification overlying the right transverse process of the third lumbar vertebra; the calyces and pelvis on the right did not appear to be dilated. The area of calcification did not appear to be within the pelvis or ureter. There was a small amount of dye seen in the calyces on the left; the kidney appeared to be definitely displaced downward, and there was a question of a pressure defect on the superior margin of the visualized calyces. There was a small amount of barium remaining in the rectum. The bladder was not definitely abnormal.

An operation was performed on the ninth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. J. H. MEANS: This patient lost weight at a time when he had a good appetite. That always makes one think of thyrotoxicosis or diabetes, but as you will presently see there is no indication that this patient had either of these diseases. We are told nothing about his past history. Whether this is because it was not important or was not taken, I cannot say. In spite of the difficulty in palpating the abdomen because of tenderness, a mass was felt in the left upper quadrant but nothing much was determined about its size.

I am supposed to guess what the surgeon did and what he found.

This fifty-year-old man had a story, first, of nine months of weight loss and, then, of three months of pain, confined to his left side. The radiation suggests a phrenic-nerve distribution, possibly arising from the diaphragm. I am not sure how much of the radiation downward was due to the patient's illness on entry because he had had sciatica in the past; it is hard to tell how much of the pain was merely a continuation of that and how much was new. Apparently the patient had some difficulty in distinguishing between them. The impressive thing is that he had widespread radiation of pain both upward and downward on the left side.

On examination the most obvious thing is a mass in the left upper quadrant, which was apparently inflammatory, at least in part, because it was tender and gave rise to spasm both anteriorly and in the costovertebral region. This mass descended with inspiration. There was also some blood chem-

istry that requires careful consideration, which I shall take up a little later, but at the moment I shall ask Dr. Holmes to give me what help he can.

DR. GEORGE W. HOLMES: I can perhaps tell you some of the things it cannot be.

DR. MEANS: I should like to learn all I can about the mass—where it is, how big it is, what shape it is, what its anatomic relations are and whether it involves the colon, kidney or spleen. I want to know if there is any evidence of tuberculosis in the chest, and all I can about the skeleton—whether there are any places giving a moth-eaten appearance that might suggest myeloma or metastatic malignant disease or tuberculosis.

DR. HOLMES: I am afraid you are going to be disappointed.

DR. MEANS: If you rule them out that would be helpful.

DR. HOLMES: I shall take the chest first. There is a definite variation from the normal in the lower left lung field that has the x-ray appearance of localized atelectasis; such a condition might be due to the fact that the diaphragm is high on this side, pushed up by the mass below. I do not believe it is tuberculosis or any other active infection.

DR. MEANS: Is there any evidence of tuberculosis elsewhere in the chest?

DR. HOLMES: No; he has thickened and rather peculiar looking lung markings in both sides of the chest.

DR. MEANS: Has he got emphysema? He had some wheezing and musical rales.

DR. HOLMES: I can say the picture is consistent with emphysema but not that he actually had it. He has the increase in anteroposterior diameter often seen in emphysema.

DR. MEANS: He probably had an emphysema, but I do not believe it is very important in the total situation.

DR. HOLMES: He has a normal-shaped heart, and no more change in the aorta than he has a right to have.

DR. MEANS: Nothing abnormal in the mediastinum?

DR. HOLMES: No.

DR. MEANS: What about the dorsal spine? Is that all right? He was fifty years old.

DR. HOLMES: The spine is not unusual for a man who has done heavy work up to the age of fifty. It is the spine you often see in old people or people with emphysema. From the films I do not believe that arthritis played a very important part.

DR. MEANS: What about the mass in the abdomen?

DR. HOLMES: In the left upper quadrant is a rather indefinite area of dullness.

DR. MEANS: What about the kidneys and spleen?

DR. HOLMES: I cannot point them out on any of these films. I cannot even be certain of the mass, but I think there is a suggestion of it.

DR. MEANS: You are not sure he has a mass?

DR. HOLMES: No; but I think he has one.

DR. MEANS: This is very helpful in a negative way. At least, I believe it is.

I had various thoughts after studying this record. Certainly there was a mass. Dr. Holmes says there probably was one, and the man who did the physical examination says there was. I must accept as fact that there was a mass. Also, this mass was definitely tender and gave rise to spasm. We may say then that there was an inflammatory mass in the left upper quadrant. It was not spleen, and I get the impression from the various facts given that it might have been attached to the kidney, although probably it was not kidney alone. Since this malady began rather insidiously with pain, followed eventually by fever, and then there turned out to be a mass in the neighborhood of the left kidney, I thought first of a perinephritic abscess. As I pursued the abscess idea farther, the possibility of subphrenic abscess on the left side occurred to me. The diaphragm was high and atelectasis had been produced. Moreover there was pain that radiated to the left shoulder blade. I found it hard, however, to reconcile this diagnosis with the pain that radiated to the groin and flank and to the inner aspect of the leg. Therefore I thought of the possibility of psoas abscess arising from spinal causes of some sort. Dr. Holmes did not find any evidence of tuberculosis in the spine. By the way, Dr. Holmes, can you tell me something about the psoas muscles? Is there any evidence of psoas involvement?

DR. HOLMES: No.

DR. MEANS: I think we can therefore dismiss the possibility of psoas abscess, but there remain those of perinephritic or subdiaphragmatic abscess. What other possibilities are there? Could he have had anything arising from the splenic flexure of the colon? I suppose he could, but I do not know precisely what.

DR. HOLMES: There is pretty good evidence that there is no intrinsic disease of the colon.

DR. MEANS: Dr. Holmes says we can rule out the colon. That is very helpful.

I believe in all probability that the operation was exploration and drainage in the region of the mass. But there are a number of other points that we must consider before closing the matter.

The blood chemistry is interesting. A blood calcium of 12.7 mg. is above the upper range of

normal. The phosphorus was on the lower border of normal. The phosphatase was definitely elevated. These findings make one think strongly of hyperparathyroidism, and yet I cannot make that diagnosis with any degree of assurance. I cannot reconcile it with the rest of the picture. There is no other evidence of hyperparathyroidism — no osteitis fibrosa cystica or any kidney lesion of the sort you get in hyperparathyroidism. I think the blood findings must be due to something else.

What else could they be due to? Multiple myeloma perhaps. The calcium may be elevated in this disease. I am also told, however, that the phosphorus is usually elevated. The serum protein in this patient was 5 gm., within normal limits, but on the low side. In myeloma it is usually elevated. Furthermore, there is no other evidence of myeloma. It is a very obscure disease and sometimes turns up at autopsy, not having been suspected in life. However, I think it is unlikely here.

I was intrigued by the weight loss, which preceded the rest of the illness by six months. A progressive loss of 30 pounds certainly cannot be laughed off, and always makes one think of some disease like tuberculosis, thyrotoxicosis or cancer.

I thought of the possibility of cancer of the kidney, and I wondered if one could get suppuration secondarily. Is it fair for me to ask?

DR. MALLORY: About a month ago we had a case of a large abscess inside a hypernephroma of the kidney.

DR. MEANS: I thought of that possibility here. It probably is not that though, because I thought of it.

Lymphoma is an insidious affair that also has to be thought of. I do not believe it is, although it could be. Certainly they would not have operated if they knew it was lymphoma, and even if it turns out to have been a tumor, I believe that there must have been some inflammatory process associated with it. I think, although I am by no means certain, that there is enough evidence to make a guess that he had an accumulation of pus and that this mass was an abscess. My first choice is a perinephritic one, and my second choice subdiaphragmatic.

I am quite prepared to be told that he had a cancer somewhere, but we have no evidence of metastasis anywhere in the body to help us on that. The prostate was said to have been enlarged, but the description of it does not sound like that of malignant disease. There is nothing in the gastrointestinal tract by x-ray examination, although he did have a few symptoms pointing in that direction. I do not believe he had hyperparathyroidism. What else could give him the changes observed

in the blood chemistry? He had been immobilized to some degree in a support, and Dr. Albright has shown us that immobilization will lead to rapid osteoporosis with atrophy of disuse of the bones and an outpouring of calcium. If the kidneys are not adequate, there is a high calcium but also a high phosphorus. This patient's kidneys were all right, so I think we may dismiss such an explanation. I am at a loss to explain the blood findings, and I am not going to attempt to explain them any more than I have indicated. I am content to say that I think we shall not be told that the surgeon explored this man's neck for a parathyroid tumor, and I expect that we shall be told that the operation was for the purpose of investigating the mass in the left upper quadrant. I believe that he found a perinephritic abscess, perhaps secondary to a carcinoma of the kidney.

DR. MALLORY: Have you anything further to add, Dr. Holmes?

DR. HOLMES: I should suspect that this patient's trouble was in the region of the upper pole of the kidney,—between it and the diaphragm,—and the first thing I should think of is a tumor arising from the kidney that became infected.

CLINICAL DIAGNOSIS

Retroperitoneal tumor?

DR. MEANS'S DIAGNOSIS

Perinephritic abscess, perhaps secondary to renal carcinoma.

ANATOMICAL DIAGNOSES

Carcinoma of body and tail of pancreas, with metastases to peritoneum, liver, mesenteric and retroperitoneal lymph nodes and lung and with extension to posterior portion of stomach.

Thrombosis of splenic and left main renal veins.
Pulmonary congestion and edema, minimal.
Hydrothorax, left, minimal.

Cholecystitis, chronic.

Cholelithiasis.

Arteriosclerosis: aorta, moderate, with calcification; pulmonary artery, moderate.

Healed pyelonephritis, right.

PATHOLOGICAL DISCUSSION

DR. MALLORY: The operation was merely a peritoneoscopy. The preoperative diagnosis was cancer in the left upper quadrant. The surgeons did not commit themselves more closely than that. The possibilities of lymphoma and carcinoma of the pancreas were mentioned. Dr. Benedict, when he looked in, saw obvious cancer implants scattered

over the peritoneal surfaces but was entirely unable to determine the primary site of the tumor.

The man went rapidly downhill, and when he came to autopsy, a huge tumor mass was found replacing the distal two thirds of the pancreas. The head of the pancreas was normal. The tumor was in such a place that it obviously did depress the duodenum, a fact that the radiologist spotted. It was large enough to have pressed on the pelvis of the left kidney, causing a little deformity, and also large enough to have elevated the diaphragm. It had invaded the serosa of the stomach but had not penetrated the muscular layers. There were extensive metastases in the liver, and one metastasis in the lower lobe of the left lung. The splenic vein was thrombosed, but the spleen was not enlarged and showed no evidence of infarction. The left renal vein was likewise thrombosed, and this kidney was enlarged, deeply congested and showed considerable tubular degeneration. The right kidney was small and deeply pitted with the scars of an old healed pyelonephritis. It is possible, therefore, that there was more renal insufficiency than was apparent from the clinical record. Unfortunately we were not informed of the chemical findings before we did the autopsy and did not investigate the parathyroid glands. The bone marrow, so far as examined, was negative.

CASE 28472

PRESENTATION OF CASE

First admission. A fourteen-month-old male child was admitted to the hospital because of generalized edema.

Two weeks prior to admission the child was found to have wet himself more frequently than usual. Ten days before, following a diarrhea for two days with loose, watery, brownish-green stools, the mother noticed puffiness about the eyes, which continued to the time of admission. Two days before, the abdomen became prominent and edema of the legs appeared. At that time, the child became "cranky." The family physician found albumin in the urine and therefore advised hospitalization.

The family and past histories were noncontributory.

Physical examination revealed a fat, fussy infant with edema about the eyes and slight edema of the lower extremities. The mucous membranes of the nose were somewhat pale and boggy. The eardrums were slightly thickened. There was some mucus in the posterior pharynx. The pharyngeal lymphoid tissue was slightly edematous. The examination of the lungs and heart was negative.

The abdomen was not prominent, and there was no edema in the abdominal wall or demonstrable scites.

The temperature was 99°F., the pulse 90, and the respirations 20.

The urine had a specific gravity of 1.040 and gave a +++ test for albumin. The sediment contained an amorphous albuminous precipitate, hyaline and fatty casts, occasional white cells and epithelial cells, and very rare red cells. The serum nonprotein nitrogen was 38 mg. per 100 cc., and the protein 3.9 gm.

On the second day the child's temperature was elevated to 101.5°F. Against advice the parents took the child from the hospital.

Second admission (four months later). The child was readmitted because of fever and diarrhea. One week before entry the patient had a slight head cold with a nasal discharge. Four days before, he fell out of the carriage, hit his head on the handle bar and had a brief nosebleed. Three days before, the child became febrile, the temperature ranging from 101 to 104°F. The next day diarrhea developed and there were as many as ten watery stools a day containing mucus and questionable small amounts of blood. During the three days of illness the patient's mother believed that the edema had diminished and that the urine volume had increased. During the twenty-four hours prior to entry, the family physician treated the patient with sulfanilamide.

Physical examination revealed a well-developed and well-nourished child who was acutely ill. He had a loose cough with some retraction of the chest with respirations. There was a contusion in the left temporal region, with some ecchymosis, and swelling about the eyes. The left cardium was gray and shiny, with no fullness. The chest was resonant except for a questionable area of dullness at the right base posteriorly; no rales were audible. The diaphragms were high. Examination of the heart was negative. There was moderate distention of the abdomen, and a fluid wave with shifting flank dullness could be demonstrated. The child seemed to complain of pressure over the abdomen more than from a comparable degree of pressure on other parts of his body. Peristalsis was diminished. There was marked pitting edema of the scrotum and legs.

The temperature was 103°F., the pulse 123, and the respirations 20.

The examination of the blood revealed a red-cell count of 2,780,000 with a hemoglobin of 11.5 gm., and a white-cell count of 7400 with 61 per cent polymorphonuclears. The urine was acid in reaction, and had a specific gravity of 1.020, with a +++ test for albumin. The sediment contained

frequent hyaline and finely and coarsely granular casts and 8 red cells, 5 white cells and 2 epithelial cells per high-power field. The stool was brown and guaiac positive. The serum nonprotein nitrogen was 28 mg. and the sugar 108 mg. per 100 cc. The blood sulfanilamide level on admission was 7.8 mg. per 100 cc. A stool culture was negative for pathogens. An x-ray film of the skull showed no definite evidence of fracture. A chest roentgenogram revealed some density in the medial portion of the left lung. A flat plate of the abdomen showed no evidence of dilated intestinal loops.

The sulfanilamide therapy was continued. The following morning the temperature had fallen to 101°F., but the respirations were still elevated. The child was taking fluids better and urinating, and during the day two stools of normal consistency were passed. Although the pulse was rapid, the quality was good, and there was no evidence of a disturbance in the peripheral circulation. Because of the fall in temperature, it was decided to delay shifting from sulfanilamide to sulfadiazine because of the greater danger of renal irritation and of anuria associated with the latter drug. The white-cell count was 6000, and the hemoglobin 10.1 gm. The sulfanilamide level was 9.2 mg. per 100 cc. The child was given a transfusion of 250 cc. of compatible whole blood.

During the course of the afternoon the temperature rose to 103°F. and the decision was made to substitute sulfadiazine for sulfanilamide therapy. In the early evening, abdominal distention increased and a rectal tube was inserted with some results. During the night some of the distention was relieved by belching and again by the rectal tube. At 7:00 in the morning the temperature was 101°F., the pulse and respirations were still elevated and the abdomen was still distended. The child had taken fluids in sips during the night without vomiting and had just voided. At 8:30 the nurse left the room for a few moments; on returning she found the baby had vomited and had ceased breathing.

DIFFERENTIAL DIAGNOSIS

DR. WILLIAM W. BECKMAN: Certain signs are present at both admissions of this child, and, although the record does not state so specifically, I think it is safe to assume they were present in the interval between admissions. These were edema, albuminuria, cylindruria and hypoproteinemia, which constitute the most important features of the nephrotic syndrome, and I think one has to make that clinical diagnosis in this case.

The pathological diagnosis is somewhat more difficult because several types of renal pathology

have been found to be associated with the clinical entity known as the nephrotic syndrome. The first one reported was, I suppose, secondary syphilis. I do not believe that is important here for although there is no mention of any serologic test, there are no stigmas or other evidence of congenital syphilis, and nephrosis is such a very rare manifestation of syphilis that we do not have to consider it seriously.

Another not too uncommon cause of the nephrotic syndrome is intoxication with heavy metals, such as mercury. At the time of first admission one could have suspected that the child had taken mercury, unknown to the parents of course, because gastrointestinal symptoms, such as diarrhea, are typical of mercury intoxication. But a duration of four months with chronic nephrosis is too long for mercury intoxication, and we can rule it out on that basis.

The most difficult things to differentiate are the so-called "nephrotic stage" of glomerulonephritis and the "true nephrosis" of Volhard and Fahr. The only thing in favor of glomerulonephritis is the fact that there were red cells in the urine. Some writers say that if any red cells are present in the urine the diagnosis of nephrosis cannot be made. I think that is an extreme point of view, and I am sure there are published cases of true lipid nephrosis with red cells observed some time in the course of the disease. Gross hematuria is rare, but a few red cells such as this are not sufficient evidence to rule out lipid nephrosis. One datum that would be of interest and use in making the diagnosis of chronic nephritis is the blood pressure, but the pediatricians assure me that blood pressures of fourteen-month-old irritable infants are valueless. That has to be dispensed with in this case. I should also like to have evidence of nitrogen retention, as indicated by an elevated nonprotein nitrogen, to establish the diagnosis of glomerulonephritis. This child did have an elevated nonprotein nitrogen at the time of the first admission, but that could be accounted for on the basis that he probably was oliguric owing to the fact that he was forming edema at that time. The high specific gravity in the urine is further evidence of this. The nonprotein nitrogen of 38 mg. per 100 cc. was most probably due to urinary suppression. Then, on the second admission, the nonprotein nitrogen was within normal limits, whereas I should expect that, if this were chronic nephritis, the nitrogen retention would have progressed over the four months' period. So I think the best diagnosis for the underlying pathology is true lipid nephrosis. There is one prominent feature of lipid nephrosis that is not mentioned, namely, the blood lipids. In this hospital, we usu-

ally measure the cholesterol, which is elevated as all the lipids are.

DR. ALLAN M. BUTLER: It was not done.

DR. BECKMAN: That is one more constant feature of the syndrome. It may be present with chronic nephritis, but it always is with a true lipid nephrosis. I think that diagnosis explains most of the things in this case except the terminal event. Diarrhea, which was a prominent symptom, is common in nephrosis, probably owing to edema of the intestines.

The cause of the final incident must be determined. If we assume that the child had lipid nephrosis, we know that his resistance to infection was markedly diminished and certainly the terminal episode, on the basis of the fever, seems to have been infection, which is very hard to localize from the facts given in the abstract. The only lead from physical examination is that the abdomen was more tender than any other part of the body, but that is vague to say the least. There might be something in the x-ray films that would help.

DR. GEORGE W. HOLMES: I am afraid these x-ray films are not going to help much, except in a negative way. I do not see anything wrong with the chest. Some mention was made of a shadow on the left, but I do not see anything there that looks abnormal. The diaphragm is high, and the stomach is distended with gas. A film of the abdomen shows nothing remarkable and the skull films are negative.

DR. BECKMAN: Most infections in the course of lipid nephrosis are caused by the pneumococcus. No bacteriologic data are given in the record except a stool culture, which was negative, but I should guess that this infection was probably due to a pneumococcus. On the basis of the fact that the abdomen was more tender than anything else, I should say there was a pneumococcal peritonitis. That is the commonest complication and commonest cause of death in nephrosis. Usually it is one of the higher types of pneumococcus, which inhabit the normal nasopharynx and which are rarely pathogenic except in a situation where resistance to infection is greatly diminished. The normal white-cell counts throughout the course of the illness are characteristic of nephrosis. That seems to be another manifestation of the diminished resistance to infection that these patients exhibit.

The actual mechanism of death I cannot make out, but I presume it was sepsis and that the same organism found in the peritoneum was found in the heart's blood at the time of autopsy.

DR. ROBERT R. LINTON: I notice that this child had a guaiac-positive stool. Has that any significance?

DR. BECKMAN: He had frequent diarrhea, perhaps with resulting irritation.

DR. BUTLER: This child is an example of the problem of intestinal distention in patients with nephrosis. The child with nephrosis that has no infection and no anatomic cause for intestinal obstruction often has an acute bout of gastrointestinal distention, sometimes with vomiting, but almost always with refusal of food and diminished peristalsis. When this particular child entered the hospital we pictured him as one who had an acute upper-respiratory infection, possibly with a peritonitis. The question whether or not peritonitis was present seemed quite doubtful, at least from the physical findings. Peristalsis was present, formed stools were passed, and the abdominal tenderness was not definite. On the first day he seemed to improve with sulfonamide therapy and the temperature came down. We were confronted with the dilemma of using the best drug for a possible pneumococcal infection, namely, sulfadiazine, or of being satisfied with a less effective drug, namely, sulfanilamide, to lessen the chance of causing renal irritation, since one always hesitates to give sulfadiazine or sulfathiazole to a patient who is very oliguric and already has renal difficulty. When the child did not seem to be so well, we decided to put him on sulfadiazine and did. The night preceding death, when the temperature went up and the distention increased, arrangements were made with the surgical service at 7:00 a.m. to tap the child to learn further about the organism causing the peritonitis, with the idea of giving type-specific serum if indicated. In a child like this, when there is a question of peritonitis and abdominal distention, the peritoneal tap should be done as a surgical procedure, since a blind tap may perforate a loop of distended bowel. In this particular case, unfortunately, the child died before this could be done. The sudden death illustrates another point about these nephrotic children. At the Children's Hospital there have been three sudden deaths in nephrotic patients when no serious infection appeared to be present. In fact, two patients did not appear critically ill, and yet within fifteen minutes they were found dead.

CLINICAL DIAGNOSES

Nephrosis.
Acute upper-respiratory infection.
Pneumonia.
Peritonitis.
Edema and ascites.

DR. BECKMAN'S DIAGNOSES

Lipoid nephrosis.
Peritonitis (? pneumococcal).

ANATOMICAL DIAGNOSES

Lipoid nephrosis.
Peritonitis, generalized (streptococcal).
Anasarca.

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: This child's kidneys were greatly enlarged, weighing 200 gm., which is about three times normal. The surfaces were generally pale and smooth, but there were focal bright-yellow spots scattered irregularly over the entire cortex. On the cut surface the cortex was very pale and rather mottled. Bright-yellow streaks could be made out in the pyramids, particularly at the points where the pyramids joined the cortex. This gross appearance made it evident that there must have been a great deal of lipid in the kidneys. Microscopically they are the type of kidneys over which pathologists love to debate whether they represent a subacute glomerulonephritis or true lipid nephrosis. There is an extremely extensive tubular damage, with much lipid in the tubules, and also many collections of lipid in the histiocytes in the stroma. There are also some obviously abnormal glomeruli—individual glomeruli can be picked out—that are quite characteristic of a true glomerulonephritis. The majority of glomeruli, however, are quite negative, except for the presence of cells that are quite distended with lipids. Sometimes the lipid deposits seem to be in the endothelial cells of the capillaries, at other times in the epithelial cells overlying the surface of the tuft. Extensive lipid deposits in the glomeruli are not, to my mind, characteristic of the early stage of glomerulonephritis. I should personally classify this kidney as a lipid nephrosis, not as a subacute glomerulonephritis, but I am quite sure that, if I put it up to a group of twenty pathologists, there would probably be about ten on each side of the question.

The peritoneum showed 800 cc. of cloudy exudate, and culture yielded alpha and beta hemolytic streptococci but no pneumococci. We were limited at autopsy to exploration of the abdomen so we cannot say what may have been present in the heart or lungs. I have an idea that even if we had done a complete autopsy we could not have explained the sudden episode.

DR. BUTLER: Streptococcal infection is often the cause of sudden death.

MASSACHUSETTS MEDICAL SERVICE

MASSACHUSETTS MEDICAL SERVICE — the Blue Shield — became available to the public on Monday, November 16. Hailed by all as the contribution of the physicians to the health of the people of the State during a war crisis, when every man-hour is needed on the production front, the Blue Shield is now an actuality; and the eyes of the public are focused on the profession to see whether it can live up to the high promises of an entirely new type of service.

What the public does not and cannot know is the endless time and effort that antedated the present organization of the Blue Shield. For three years a special committee appointed by the Massachusetts Medical Society, the sponsor of the plan,

studied similar projects both in this country and abroad, sifting each of them for the greatest merit. In the past few months, since the final plans were announced at the annual meeting of the Society on May 25, a large group of physicians, as well as industrial and business leaders, have given unselfishly of their time to make the Blue Shield a reality that would stand up under the test. Helping them was the State Commissioner of Insurance, who is well versed in the pitfalls of insurance practice.

There is no question that the new project will go down as history in medical annals. It will live not only for the service that it renders the public, but because the physicians of Massachusetts, despite the national crisis, were foresighted enough to offer a voluntary plan that helps to solve the growing problem concerning the equal distribution of medical care.

Massachusetts Medical Service began its operation with 2500 participating physicians. This is an impressive and adequate number, and one that foretells the success of the venture. Hundreds of additional signatures are needed, however, if the profession intends to go on record as a united group that is determined to solve medicoeconomic problems according to the principles of free practice and private initiative.

The profession can be justly proud of its achievement in launching Massachusetts Medical Service. Those who are not participants in this project, which is open to all licensed physicians in the State, should sign their applications without delay and return them to 230 Congress Street, Boston. In this manner, one hundred per cent of the physicians in Massachusetts can fulfill their role by standing solidly back of the forward-moving Blue Shield.

GASOLINE AND TIRE RATIONING

ELSEWHERE in this issue of the *Journal* is a copy of an open letter from the Gasoline Rationing Branch, Office of Price Administration, which was published in the "Medicine and the War"

section of the October 31 issue of the *Journal of the American Medical Association*.

By and large, there seems to be little need for calling physicians' attention to the things that they should do to conform to the regulations governing gasoline and tire rationing. Throughout the war effort, physicians have co-operated wholeheartedly: their response to the demands of the armed forces for medical officers has been superb; the needs of the Selective Service System and of the Office of Civilian Defense have been adequately met; and the increased activity occasioned by a depleted personnel in civilian and industrial medical practice has been cheerfully provided. Of course, as in any other group that represents a cross section of the general population, there are bound to be certain individuals who, because of carelessness, thoughtlessness or selfishness, will fail to "play the game." But these comprise a small minority, and the profession as a whole can be depended on to accept its responsibilities and to act according to standards that, throughout the years, have stood for patriotic and unselfish devotion to whatever cause, medical or otherwise, it has adopted.

MEDICAL EPONYM

SHIGA-FLEXNER BACILLUS

Kiyoshi Shiga (b. 1870), while assistant at Kitasato's Institute for Infectious Diseases, summarized his conclusions in regard to the bacillus of dysentery in an article, entitled "Ueber den Erreger der Dysenterie in Japan [The Causal Agent of Dysentery in Japan]," dated at Tokio, December 10, 1897. It was published in the *Centralblatt für Bakteriologie, Parasitenkunde und Infektionskrankheiten* (Abt. I—23:599, 1898). He speaks of the failures of other investigators who had made use of animal experimentation, attributing this to the fact that most experimental animals are not susceptible to human dysentery. A portion of the translation follows:

On this account, following the suggestion of Professor Kitasato, I have investigated the subject of dysentery from another angle, namely, as follows: The question arises whether one may not find a micro-organism in the stools of patients suffering with dysentery which will show an agglutinating reaction with their blood serum, such as Widal first demonstrated with typhoid

bacilli and the serum of patients suffering with typhoid fever. I have made careful bacteriologic examinations of the stools and internal organs of 36 cases of dysentery, and have constantly found one and the same bacillus, which showed a clear-cut agglutinating reaction in the presence of serum of patients with dysentery. . . . I believe that we may probably consider this bacillus as the cause of dysentery.

He describes the cultural characteristics of the organism and further states that the serum of a person injected with the dead culture likewise shows the agglutinating reaction.

On April 12, 1900, Dr. Simon Flexner (b. 1863), professor of pathology at the University of Pennsylvania, delivered a lecture before the New York Pathological Society, entitled "On the Etiology of Tropical Dysentery." This was published in the *Bulletin of the Johns Hopkins Hospital* (11: 231-242, 1900). After an exhaustive account of his investigations and a complete review of the symptomatology, bacteriology and pathology of tropical dysentery, including reference to Shiga's work, he concludes:

I think I have shown that tropical dysentery consists of a bacillary and an amebic form, separable in their early and their later stages by their clinical histories, their etiology and pathological anatomy.

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE ON MATERNAL WELFARE

ANALYSIS OF CAUSES OF MATERNAL DEATH IN MASSACHUSETTS DURING 1941

EMBOLISM

As the tabulation that appeared in the October 15 issue of the *Journal* showed, 39 cases were allocated to embolism as the primary cause of death, and this number is exceeded only by those deaths attributed to sepsis and medical causes.

Five cases were associated with cesarean section. The first was that of an elderly primipara, who after a classical section ran a slight temperature until the thirteenth day, when there were definite pain and redness in the calf of one leg. Twenty minutes later, following an attack of cyanosis and dyspnea, the patient became pulseless and expired. This embolus undoubtedly originated from a pelvic thrombophlebitis.

The second case was associated with a placenta previa. This patient had had no prenatal care until the eighth month, when she summoned a physician because of painless bleeding. The section was followed by a supravaginal hysterectomy.

Sepsis developed postoperatively; and although sulfonamide therapy was instituted and several transfusions were administered, death occurred suddenly following an acute pain in the chest on the twenty-eighth day after delivery. The supravaginal hysterectomy was done because of a very adherent placenta, which was described as an accreta.

The third case was that of a multipara who had had a marginal placenta previa diagnosed by vaginal examination; because of the resulting bleeding a cesarean section was immediately done under spinal anesthesia. Forty minutes after the beginning of the operation the patient suddenly became blue and died. This was probably an embolic death, although no autopsy was performed.

The fourth patient, who had had a previous cesarean section, died very suddenly shortly after the operation. There was no history of hemorrhage, and the diagnosis of embolism is undoubtedly correct.

The fifth case was also a repeat cesarean section, which was followed by a normal convalescence until the fourteenth day, when the patient developed a pain in her chest; three days later, while combing her hair, she slumped in the chair and died immediately. Undoubtedly this was a true case of embolism.

There were 10 cases in this series associated with operative vaginal delivery. The first occurred in a thirty-year-old multipara with twins and is an example of poor obstetrics. Labor did not start until the fifth day after premature rupture of the membranes, and attempts at forceps delivery and then at version were unsuccessful, a diagnosis then being made of a hydrocephalic baby, which was finally delivered by craniotomy. The second baby was delivered easily. Infection resulted, and in spite of sulfonamide therapy and intravenous injections of plasma, death occurred suddenly on the twentieth day after delivery. It is quite likely from the history that the infection involved the peritoneum, which suggests a possible rupture of the uterus.

The second case was associated with premature separation of the placenta, which was treated by hysterectomy. The patient was transfused four times. Infection developed, and in spite of hemotherapy, death occurred precipitately six days postoperatively. The prenatal care in this case was inadequate, the patient having been seen only once before the catastrophe; but it is doubtful whether prenatal care would have averted this fatality.

The third case was that of a patient who was delivered at home by low forceps but was moved to a hospital because of the occurrence of an em-

bolus prior to delivery of the placenta and died shortly after entry. Emboli during labor are fortunately uncommon. It is difficult to know how such a death could have been averted.

The fourth death occurred in a woman who had had six previous full-term deliveries and whose history indicated a long period of irregular bleeding. Four weeks before hospital entry a curettage had been done, the pathological report of these curettings being "necrotic placental tissue." On re-entry, because of the bleeding and the size of the uterus, which was diagnosed as a fibroid, a hysterectomy was performed and death occurred suddenly ten days postoperatively. The uterus, when opened after operation, revealed a three-month fetus. A mistaken diagnosis, of course, was the real cause of this sad catastrophe.

The fifth case was that of a patient delivered by low forceps who went into shock shortly after delivery. She was given 2 ampules of blood plasma, but death occurred shortly afterward. Post-mortem uterine palpation showed the uterus to be intact, thus ruling out rupture of the uterus. There was no history of a difficult anesthesia. Although no autopsy was performed, the suddenness of the death makes it likely that embolism was the true cause.
